Area of Hot-Air Ducts for Gravity-Circulation. A velocity of approximately one third of the theoretical velocity attainable by natural draft, due to the smaller density of the heated air, is assumed in practice in proportioning the area of the hot-air ducts.

Example. Required the size of hot-air duct for each of the indirect radiators in the preceding examples for a first-floor installation, the effective height E being 5 ft.

Solution. The excess of temperature in the flue above the external air is $100 - 0 = 100°$. The theoretical velocity in the duct, from Table XXVIII, is $8.1 \times 60 = 486$ ft per min. The actual velocity is approximately one third of this, or 162 ft per min. The weight of air per minute passing through the flue is 23 lb, or

$$23/[0.071 \text{ (density at } 100°)] = 324 \text{ cu ft}$$

The required area of the flue is therefore

$$324/162 = 2 \text{ sq ft} = 288 \text{ sq in}$$

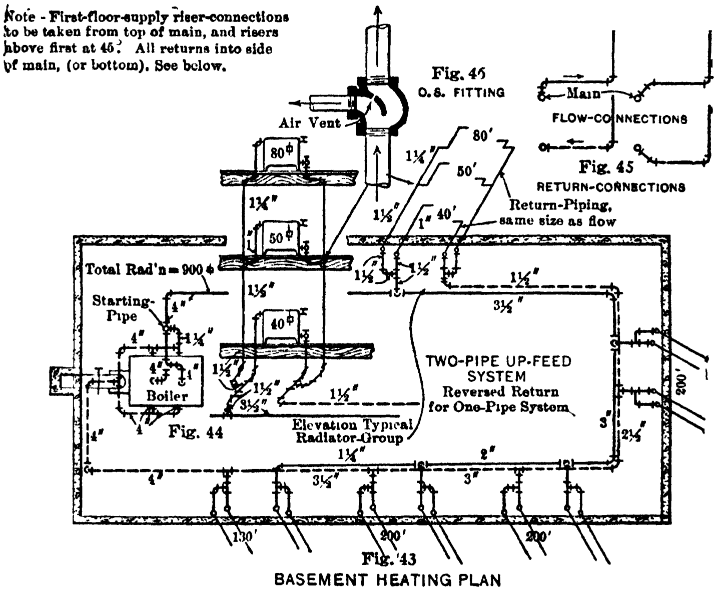
The gross area of the register-face must be approximately 1.8 this amount or 518 sq in, to obtain the same free area through the register-grill as exists in the flue or duct. Sizes of standard registers are given in the section on Furnace-Heating.

Direct Hot-Water Heating

Systems in Use. Systems for heating with direct hot-water radiators, like the direct steam heating systems, may be divided into two general classes, the first of which includes all those systems OPERATING BY GRAVITY ONLY, depending on the difference in density of the water-columns in the flow and return-lines to cause circulation. The second class includes those systems in which a FORCED CIRCULATION is maintained by means of a pump placed on the return-line just before it enters the boiler or heater. These latter systems are employed usually only in large installations or in district-heating service.

Gravity Hot-Water Heating Systems. The gravity systems are divided into the UPFEED SYSTEMS, using basement-mains, and the DOWNFEED SYSTEMS, using overhead or attic-mains. The upfeed systems may have either a one-pipe basement-main or two-pipe basement-mains, and the latter type may have either a DIRECT or a REVERSED return-main. (See Figs. 43 and 44 for reversed return.) The downfeed systems may have either SINGLE OR DOUBLE RISERS. Either system may be operated with an OPEN or CLOSED EXPANSION-TANK, as shown in Figs. 43 to 46. In general, the downfeed or overhead systems are more positive, permit the use of smaller mains and risers, and provide for the automatic removal of air from the radiators and piping. It is necessary, however, that the head room or clear space in the attic should be at least 4 or 5 ft if the overhead mains and branches are to be properly installed. It is sometimes possible to run the overhead mains at the ceiling of the top floor, and in such cases the above restriction does not apply. Mains run in attics must be well insulated to prevent freezing. The underfeed systems are used where basement-space is available, and of little or no value, and the radiation is located on two or more floors; or where attic-space is so limited that it would not be possible to install overhead mains and branches. Underfeed systems are liable to prove unsatisfactory in buildings less than two stories in height, as the motive head with radiators on the first floor only is so slight that faulty or deficient circulation is quite likely to result.

The Upfeed One-Pipe System. The upfeed one-pipe system is in general use today, and is employed almost exclusively by the United States Treasury and War Departments whenever upfeed hot-water systems are to be installed. In this system, as shown in Figs. 48 and 50, the supply-main rises close to the basement-ceiling just above the boiler and grades down in the direction of flow, with a uniform grade of ¾ in in 10 ft. Branches are taken from the top of this main for supplying flow-risers and the return-branches are made into the side or bottom. (Fig. 45.) Flow-connections should always be made from the top, or at an angle of 45° in the case of branches near the boiler,



Figs. 43, 44, 45 and 46. Hot-water Heating. Two-pipe Up-feed System

or for branches supplying only upper-floor radiators. It will be seen that in the case of branches supplying radiators on all floors the upper-floor radiators may be made to PULL or augment the circulation of the first-floor radiators by taking the basement-branch for the former from the side of the branch running to the latter radiator. The first-floor branch is usually run full size all the way to favor the lowest radiator, as shown in Fig. 50. After having served all the radiator-branches the main drops and returns to the boiler, continuing the same size for the entire circuit. Connections (Fig. 48) to radiators should be made at the TOP on the supply-end, using a union elbow, and at the BOTTOM on the return-end, using a quick-opening hot-water radiator-valve with union connection. By this arrangement only one valve is required to control the radiator. Since the temperature of the water in the one-pipe main gradually drops, due to the return of water at a lower temperature from the radiators served in the course of the main around the building, it is advisable to increase the last radiators on the main from 5 to 10% in area and to increase the size of

4½	1 325	1 400	1 485	1 560

Table XXX was compiled by J. J. Hogan, and is to be used for either one or two-pipe work.

The Upfeed Two-Pipe System. The upfeed two-pipe system is also in very general use, and if installed with a REVERSED RETURN, as shown in Figs. 43 and 44, will give good results. If a DIRECT RETURN is used so that the water circulates first through the radiators nearest the boiler, and then through each succeeding group in turn, the ends of mains will be slow in warming up, the last radiators may be cold, and the system prove unsatisfactory. With the REVERSED-RETURN SYSTEM each group of radiators has exactly the same length of water-travel, and hence the resistance to be overcome is practically the same, irrespective of the distance of the radiator-group from the boiler. It will be noted that the return begins at the first radiator served and flows in the SAME DIRECTION as the flow-main, increasing in size while the latter decreases. The flow-main grades UP uniformly ¾ in in 10 ft, and the return grades DOWN toward the boiler with the same pitch. Pipe-sizes may be taken from Tables XXIX and XXX as in one-pipe work, and the main-size reduced or increased as rapidly as the change in radiation supplied will permit. It is also customary in government work to install a STARTING-PIPE (Fig. 43), between the main flow and return at the boiler, in underfeed systems. This pipe ranges from 1¼ to 2½ in in size, depending upon the capacity of the boiler, and is intended to assist in the establishment of an initial circulation between flow and return-headers, even before the water in the mains is moving.

Equalization-Table. In Federal-building work N. S. Thompson makes use of the following Equalization-Table in proportioning mains and risers serving more than one radiator in both upfeed and downfeed systems. The equalizing-numbers represent the relative capacities of the different sizes of pipes for

Table XXXI. Equalization-Table for Mains and Risers

in	in	in	in	in
½ = 2	¾ = 5	1 = 10	1¼ = 20	1½ = 30
2 = 60	2½ = 110	3 = 175	3½ = 260	4 = 380
5 = 650	6 = 1 050	7 = 1 600	8 = 2 250	

Example. A 1¼-in, 1½-in and 2-in pipe have a total value of 110 units, and hence are equivalent in carrying capacity to a 2½-in main.

the same friction-pressure loss per 100 ft of run, and are proportional to the 5/2 powers of the diameters. Thus the weight of water flowing varies as shown by the relation, $W = Kd^{5/2}$, in which W = weight, I = a constant, and d = pipe-diameter.

Details of Piping Systems and Connections for Direct Hot-Water Heating. The distinctive piping-details of each system of hot-water heating have been discussed under that system, as described in the preceding paragraphs. In general all main piping and branches must be UNIFORMLY GRADED, as already indicated, and ample provision made for EXPANSION and CONTRACTION, and the ready REMOVAL OF AIR from all parts of the system. Air-traps or pockets in a hot-water system are fully as serious as water-pockets in a steam system. Hence a hot-water main grading down in the direction of flow cannot be relayed unless an air-outlet is provided at the top of the relay. If the main is reduced in size at any point an ECCENTRIC FITTING must be used to keep the TOP of the large and small main in the same plane and avoid an air-pocket. Not only must all the piping be designed to permit the removal of air, but FREE AND COMPLETE DRAINAGE of water must be provided for as well, so that when the drain or blow-off cock is opened at the boiler the entire system can be emptied of water. If branch-mains are taken from a HEADER at the boiler

they must all rise to the SAME ELEVATION so that the tops of all the branches will lie in the same plane as they start away from the boiler. The fittings on all main piping and branches must be of the long-sweep pattern, and all pipe should be carefully reamed to remove burrs and sharp edges. Where the same riser supplies radiators on two or more floors the branches to the radiators on the intermediate floors may be connected with special tees (Fig. 46) known as O. S. FITTINGS, with a deflector arranged to divert the current of flow into the outlet of the tee, and thus favor the radiators on the intermediate or lower floors. By using TOP-FLOW and BOTTOM-RETURN CONNECTIONS at each radiator it is possible to positively control each unit by a single valve, except for the slight circulation intended to prevent freezing, which takes place through the $\frac{1}{16}$-in-diameter hole drilled in the valve-disc or sleeve, when the valve is closed. If both connections are made at the bottom tappings, and only one valve is used, it is entirely possible that the radiator may still be supplied with hot water through the unvalved connection even when the valve is closed.

Air-Removal in Hot-Water Systems. Suitable provision must be made for the removal of air from all hot-water radiators, wherever an upfeed system is installed. Usually small air-cocks are attached to the highest point of each radiator and are periodically opened to relieve any accumulation of air. If these cocks are forgotten a radiator may become air-bound and fail to heat because of faulty circulation; hence automatic air-valves are sometimes installed for this purpose. The automatic air-valve for hot-water radiators is not very generally used, due to its liability to pass water as well as air; but a standard type, made by the Monash-Younker Company, may be mentioned.

Expansion-Tanks for Hot-Water Heating. Open-Tank Systems. The low-pressure system of hot-water heating is not a closed system, as provision must be made for expansion and contraction of the water within the system. An open tank is provided at a suitable elevation, not less than 3 ft above the highest radiator, and connection made to the nearest return-riser; or preferably a separate expansion-line is run to the flow or return-main in the basement. The SIZE OF THE EXPANSION-TANK varies with the amount of water in the system, and also with the range in temperature of same, and its capacity is determined as follows:

The increase in volume of a given weight of water heated from 32° to 212° is about $\frac{1}{23}$, or approximately 4.33%; so that for every 23 gal in the system at 32°, an allowance of 1 gal must be made in the expansion-tank when the water in the system is raised to 212°. Cast-iron radiators have an internal volume of $1\frac{1}{2}$ pints per sq ft, while steel radiators and 1-in pipe hold about 1 pint per sq ft. Assuming the internal volume of the radiators to be about 50% of the entire system, we have for 3 000 sq ft of actual radiation, $3000 \times 2 \times \frac{1}{8}$ gal $= 750$ gal of water. This water will increase $\frac{1}{23} \times 750 = 33$ gal on being heated from 32° to 212°. Hence an expansion-tank of $2 \times 33 = 66$-gal capacity is necessary, the tank being made double the theoretical volume for practical considerations.

A list of expansion-tank capacities and dimensions is given in a table (included with Figs. 47 to 51), from which a commercial tank may be readily selected for systems under 6 000 sq ft. For larger systems the size of tank should be separately determined and the nearest commercial tank-size, as taken from the manufacturer's list, should be specified. These tanks should have 1 or $1\frac{1}{4}$-in top and bottom tappings with $\frac{1}{2}$-in water gauge tappings, for connecting a gauge-glass, at least 12-in long, on the side of the tank as shown in Fig. 43. The tank must be securely supported well above the highest radiator in the system, and in the larger installations special framing must often be

designed to carry the weight of tank and water. Automatic expansion-tanks equipped with a ball-cock and overflow are sometimes installed, and the altitude-gauge on boiler, and the gauge-glass and fittings on tank omitted. These tanks may be covered with hardwood and varnished if it is necessary to place them in a finished room or apartment.

Expansion-Tank Connections. The most approved method of connecting an expansion-tank to a low-pressure one-pipe system is shown in Fig. 48, where an expansion-and-vent line is run from the top of the main, at the high point just above the boiler, and connected to a return-bend just beneath the tank. A return circulating-line is taken from the other side of this bend and connected with the return-main at the boiler. The circulation of water in this loop will prevent freezing at the tank. From the top of the tank a 1¼-in vent-line is taken through the roof, and a 1¼-in overflow is taken out of this vent-line at a tee just above the tank. This overflow should discharge into an open sink or drain near the boiler so that it will be immediately evident to a person in the boiler-room, filling the system, just when the water has risen to the overflow above the tank. The movable hand on the boiler altitude-gauge can then be set to correspond with the middle of the gauge-glass, and the water-level brought to this point with the system cold. No valves should ever be installed on either the expansion or the overflow-lines, and in case the system is valved at the boiler the expansion-line must be connected on the boiler-side of this valve; and where two boilers are installed this line must be carried to a point above the waterline in the expansion-tank to prevent siphoning the water out of the entire system in case it is necessary to drain only one boiler. Expansion or vent-pipe connections must always be so made to main-piping in basement so that all air will be automatically removed from high points. Wherever possible risers or branches to risers may be used for relieving any accumulation of air in the main-piping. In SMALL INSTALLATIONS the expansion-line may be connected to the return-riser of one of the highest radiators, and no overflow other than the vent need be provided for, as shown in Fig. 51. This is a cheap method, and should not be resorted to unless extreme economy must be practised. The tank must be in the same room with the radiator to prevent freezing, as no circulation is provided for, and the overflow is simply discharged out of doors and usually upon the roof. The usual result is that an unsightly appearance is soon created.

The United States Treasury Department employs a special vent and overflow connection (Fig. 47) in cold climates, where there is liability of the vent-line freezing up if run out through the roof, due to the condensation and freezing of vapor passing out through this line. The vent-line is made only 2 ft high above the tank so that it is kept within the building, and it is equipped with a check-valve to prevent the escape of water through the same in case the tank should suddenly overflow. The closing of the check-valve will compel the excess water to pass down the overflow, and prevent the flooding of the building.

Closed-Tank Systems. The PERMISSIBLE TEMPERATURES in any hot-water system are limited by the pressure on the system, which latter factor determines the point at which boiling will take place. The pressure at any elevation in an OPEN-TANK hot-water system will vary directly with the distance below the level of the water in the expansion-tank, and hence it will be possible theoretically to carry the water in the boiler at a temperature corresponding to the hydrostatic pressure at the boiler before boiling would occur. The relation between hydrostatic head, pressure and boiling-point are given in the following table:

Table XXXII. Relation between Hydrostatic Head, Pressure and Boiling-Point

Hydrostatic head in feet.	0	12	24	37	49	61	74	87	100	113	125
Pressure in pounds per square in.....	0	5	10	15	20	25	30	35	40	45	50
Boiling-point......	212	227	239	250	259	268	274	281	287	292	298

Practically it would be quite impossible to carry temperatures in excess of 212° in any part of an open-tank system, as the high-temperature water would immediately rise into the open tank and boil. In order to overcome the limitations of the open-tank system, in which water will always boil as soon as a temperature of 212° F. is reached, various means of increasing the pressure in these systems have been resorted to in the attempt to carry a higher water-temperature in the radiators in very cold weather than would be possible with an open-tank system. These devices have usually been installed on the expansion-line, either at the boiler or else just below the expansion-tank and the static head increased by interposing a column of mercury in the path of the expanding water as it flows into the expansion-tank.

A common form of the apparatus, known as the HONEYWELL HEAT-GENERATOR, is shown in Fig. 49, in which it is seen that water entering the generator from the system will force the mercury up the inner tube *A* until a head of 20 in or 10 lb is established, at which time the entrance to this tube will be uncovered by the mercury and water or air may enter it and pass to the expansion-tank. Any excess of mercury above that required to just fill tube *A* is returned by tube *B* to the reservoir in the base. When the system cools off water can flow back down tube *A* as soon as the mercury-column drops in it, and the slight head of mercury then existing at the outlet of this tube is easily overcome by the head of water in the expansion-tank above this point. This increase of 10 lb in static pressure makes it possible to carry a maximum water-temperature of 240°, nearly 30° higher than would be possible in an open-tank system. While a temperature as high as this could theoretically be carried AT THE BOILER in an open-tank system with a static head of 24 ft, just as soon as this water rose in the system it would boil, and escape from the expansion-tank, at the same time emptying the system of water. In fact with the open-tank system the water is liable to be driven out at a temperature of 212° F. The use of pressure-generators similar to the above makes it possible to use smaller radiators in the heated rooms, as it is entirely possible to maintain steam-temperatures in the radiators whenever desired. Since higher temperatures are used, the difference between

Table XXXIII. Riser-Sizes for Honeywell System

Pipe-size inches	Capacity in square feet of hot-water radiation		
	1st floor	2nd floor	3rd floor
½	30	40	50
¾	75	100	125
1	75 up	100 up	125 up

flow and return-riser temperatures becomes greater than in the open-tank system, and hence a greater motive head exists and smaller mains and risers may be used with this system. The HONEYWELL COMPANY recommends the schedule of radiator-tappings shown in Table XXXIII.

It should be remembered that since radiators and pipes are smaller in this system there is much less water than in the open-tank system, making it more sensitive in warming up and also in cooling off. The GENERATOR should not be placed close under the expansion-tank. Otherwise than this its location may be anywhere in the expansion-line, as the same hydrostatic head is always acting in addition to the head of mercury-column.

Warm-Air Furnace Heating

The Furnace and Its Location. The method of warming or heating a building by what is generally known as a warm-air furnace is termed FURNACE HEATING. The furnace may be of a cast-iron or steel construction or a com-

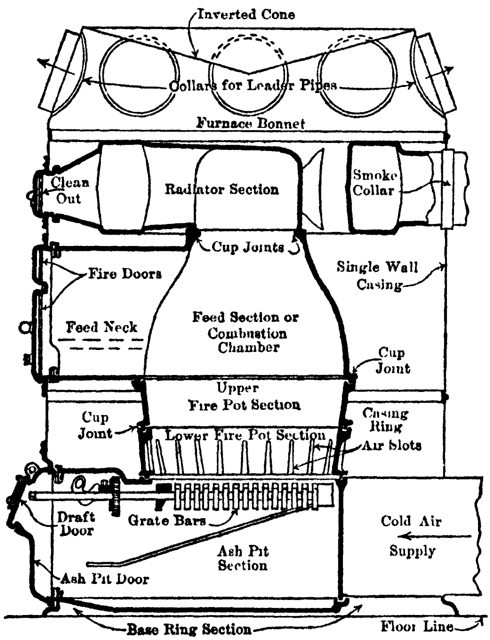

Fig. 52. Section of a Majestic Cast-iron Circular Radiator Furnace and Casing

bination of the two (Figs. 52 and 53), containing a COMBUSTION-CHAMBER, FIRE-POT and GRATE. Furnaces for soft coal are usually designed with a secondary air-supply or OVERDRAFT for admitting heated air just at the surface of the fire in order to produce a more perfect combustion of the volatile combustible gases which are liberated from this fuel immediately after firing.

This overdraft should be under positive control so that it may be checked or closed after the fuel has been coked. Soft coal may also be burned efficiently in the underfeed-type of furnace in which coal is fed from below by means of a plunger operating in a feed-chute discharging through the center of the grate. The furnace should be located in the basement in an approximately central position with reference to the rooms to be heated, and preferably toward the side or sides from which the prevailing winds blow in the wintertime. This arrangement not only favors the more exposed rooms on the floors above by shortening the leaders to these rooms, but also makes it possible to reduce the length of the cold-air duct, if one is employed, which should be run from the exposed side of the building to the cold-air pit below the furnace. Usually, however, the air is all recirculated, the recirculation register being located in the hall as shown by Figs 54 and 67, passed through the space between

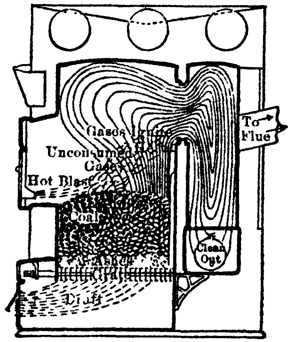

Fig. 53. Section of a Steel Furnace with Radiator and Casing

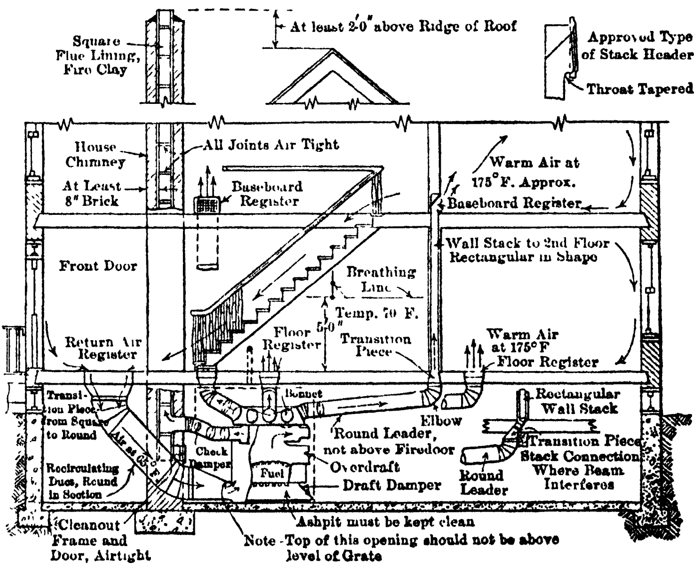

Fig. 54. Section through a Residence Showing Details of a Warm-air Heating System (See Fig. 68 for plan)

the heater and its jacket, and warmed by coming in contact with the outside heated surface of the combustion-chamber and the radiator, which is

usually just above the combustion-chamber. It is then discharged through flues connected at the top of the JACKET, FURNACE CAP or BONNET to the rooms to be warmed.

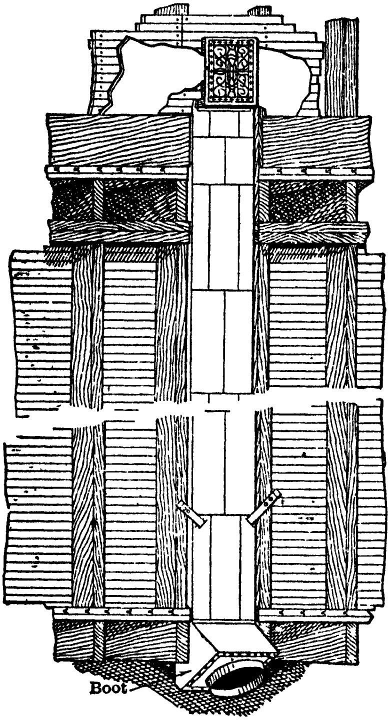

Fig. 55. Vertical Stack with Side-wall Register

Leaders and Stacks. These connecting flues are made up of two sections, (1) the nearly horizontal round pipes in the basement, known as LEADERS (Figs. 58 and 59), which connect to the COLLARS on the top or conical sides of the bonnet, and (2) the vertical rectangular pipes called STACKS (Fig. 55), which connect the BOOT at the outer end of the leader, with the double-walled REGISTER-BOX (Fig. 56) into which the REGISTER-GRILLE covering the opening into the room, is fitted. The leaders should have an upward pitch toward the base of the stack of at least 1 in per foot, and for the best results they should not be more than from 12 to 15 ft in length. The boots are made in a great variety of shapes to suit actual conditions, and are simply ADAPTERS for the purpose of changing from round leaders to rectangular stacks. The stacks are usually run between the studding of interior walls or partitions (Figs. 55 and 56), since if they are placed in outside walls the cooling effect reduces their efficiency not only in temperature of air, but also in velocity of flow. The METAL used for leaders and stacks is usually bright IX tin, although for leaders larger than 12 in, galvanized steel of No. 26 United States Standard gauge is usually employed. Since the stacks must frequently run in a 4-in stud-

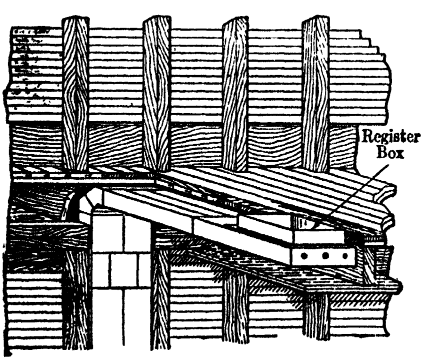

Fig. 56. Vertical Stack and Register-box

ding-space, with a net depth of about 3¾ in, every effort must be made to keep them as deep as possible; and steel lathing or expanded metal should be used in front of all such stacks, which ordinarily have only a single layer of asbestos-paper covering. A more effective insulation may be provided

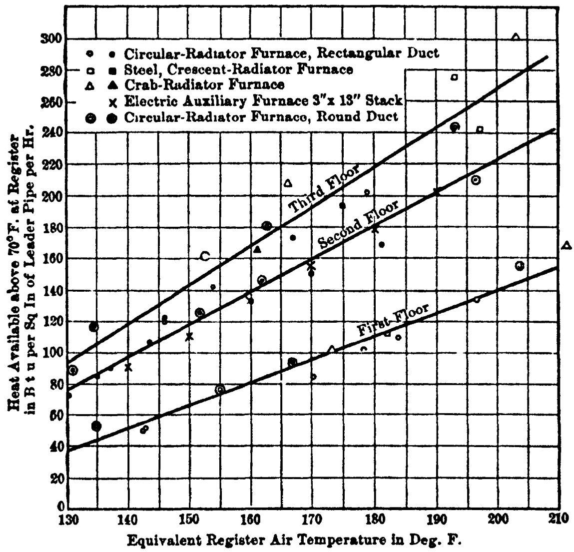

Fig. 57. Value of Square Inch of Leader Pipe Area for First, Second and Third Floors

by using a DOUBLE-WALL STACK, in which there is an air-space between the inside and outside pipes, and no asbestos covering is used. Attention of the architect is here called to the fact that in the case of large second-floor rooms to be warmed by one register, 6-in stud partitions are generally required for the first floor.

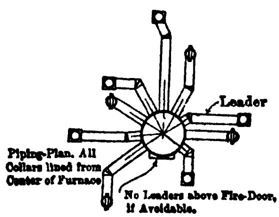

Fig. 58. Warm-air Furnace-leaders with Elbows

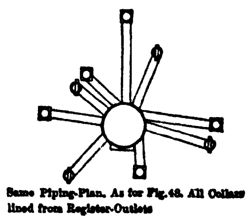

Fig. 59. Warm-air Furnace-leaders without Elbows

Commercial Ratings of Furnaces. Manufacturers formerly rated their furnaces according to the amount of space, cubical contents, in the ordinary residence-construction they will heat to 70° F. in zero weather. The actual

size of the furnace naturally depends upon the heat-transmission of the walls, floors and roofs, plus the infiltration-losses, as already explained. The claim, however, is made that these "in turn bear a reasonably uniform relation to the cubical contents of the ordinary house," with the usual proportions and ratios of wall to glass-surface, and that therefore the rating, as given, is justifiable. Tables XXXIV and XXXV were taken from the Warm Air Furnace Hand-

Table XXXIV. Approximate Capacity of Warm-Air Furnaces for Residences of Ordinary Construction in Cubic Feet of Space Heated

* The casing-diameter should be such that the minimum cross-sectional area M, between casing and radiator, will be at least 20% greater than the total cross-sectional area of all the heat-pipes, a, or $M = 1.2 \times a$ sq in.

book, published by the Federal Furnace League, an association of United States furnace-manufacturers. This association is no longer in existence. If the majority of the basement or leader-pipes exceed 12 ft in length or have less

than 1 in rise to the foot, or if more than one sixth of the outside surface of the building is glass, then the furnace should be increased one or more sizes. The size of the furnace required is now quite generally determined by the combined area of the cross-sections of the warm-air pipes. Tables XXXIV and XXXV are intended to be employed as only a rough approximation. Furnaces should always be designed on the basis of the heat-loss calculations as given in the text following.

The Design of a Gravity Warm-Air Furnace Heating-System

Recommended Procedure to be Followed. The rational design of a furnace heating-system involves the determination of the following items:

(*a*) Heat loss in Btu per hour from each room in the building.

(*b*) Area and diameter in inches of warm-air pipes in basement known as leaders.

(*c*) Area and dimensions in inches of vertical wall pipes known as stacks.

(*d*) Free and gross area and dimensions in inches of warm-air registers.

(*e*) Area and dimensions of (1) recirculating or (2) outside air supply-ducts in inches. There may be one or more of each.

(*f*) Free and gross area and dimensions in inches of recirculating registers.

(*g*) Size of furnace necessary to supply the warm air required to overcome the heat loss from the building. This size should include square inches of leader pipe area which the furnace must supply. It is also desirable to specify a minimum bottom fire-pot diameter in inches, which is the nominal grate-diameter in the case of furnaces burning solid fuel. The kind of fuel and its approximate heat value should be known.

(*h*) Area and dimensions in inches of chimney-lining and smoke-pipe. If an unlined chimney is to be used, that fact should be made clear. The height of chimney must be known as it may affect the area, and chimneys under 30 ft in height may prove unsatisfactory.

(a) Heat Losses from Building. The heat which will be required for each room in the building depends on (1) the HEAT-TRANSMISSION LOSSES through walls and glass as well as through floors and ceilings when the latter two are next to unheated spaces, and (2) the INFILTRATION OF COLD AIR through the cracks around outside windows and doors. Calculations for the heat required in Btu per hour should be made as previously indicated.

(b) Leader Sizes. A building is heated by a furnace heating-system with warm air introduced into the various rooms at some temperature higher than that to be maintained at the breathing-level, which is usually 70° F. If the difference between the entering-air temperature and the room-temperature is small, the operating head will be small and large pipes and registers will be needed, but if this difference is large the operating head will be increased almost proportionally to the new temperature difference, and smaller pipes and registers than in the first case may be used. As a result, in a gravity circulating warm-air furnace system, the size of the leader to a given room depends on the temperature of the warm air entering the room at the register. A reasonable air temperature at the registers must therefore be agreed upon before the system can be designed. The National Warm Air Heating Association has approved as satisfactory an average air temperature of 175° F. at the registers. At this temperature the heat-carrying capacity (heat available above 70° F.) per square inch of leader pipe per hour for first, second or third floors is shown by Fig. 57 at 175° F. to be 104, 172 and 208 Btu respec-

tively, based on tests at the University of Illinois. For average calculations,* the values 111, 167 and 200 will simplify the work and may be satisfactorily substituted for these heat-carrying capacities. If H represents the total heat to be supplied to any room, the resulting equations are:

$$\text{Leader areas for first floor, square inches} = \frac{H}{111} = \text{approximately } 0.009\,H \quad (1)$$

$$\text{Leader areas for second floor, square inches} = \frac{H}{167} = \text{approximately } 0.006\,H \quad (2)$$

$$\text{Leader areas for third floor, square inches} = \frac{H}{200} = \text{approximately } 0.005\,H \quad (3)$$

If it is desired to design for a lower warm-air register temperature, say 160° F., the original values 104, 172 and 208 become 82, 140 and 168 (Fig. 57 at 160° F.), and the resulting equations are:

$$\text{Leader areas for first floor, square inches} = \frac{H}{82} = \text{approximately } 0.012\,H \quad (4)$$

$$\text{Leader areas for second floor, square inches} = \frac{H}{140} = \text{approximately } 0.007\,H \quad (5)$$

$$\text{Leader areas for third floor, square inches} = \frac{H}{168} = \text{approximately } 0.006\,H \quad (6)$$

These equations are applicable to straight leaders from 6 to 8 ft in length. Longer leaders must be very thoroughly covered or else the vertical wall stacks must be increased in area above approximately 75% of leader area, as discussed under Stack Sizes. If some provision is not made for these longer leaders, the register air temperature may be much lower than anticipated and the room may not be properly heated.

While Fig. 57 takes care of the drop of temperature in straight leaders up to 8 ft in length connected to stacks having about 75% the area of the leader, the designer must make allowances for all other conditions.

In addition to the effect of leader length and register air temperature the drop in temperature between furnace bonnet and register face is affected by the stack-leader ratio and the stack construction, whether single or double wall, for various stacks. The value of high stack-leader ratios and double-wall pipe to upper floors is very apparent in its effect on reducing the temperature drop between bonnet and register face.

Leader sizes should in general be not less than obtained by Equations (1) to (3), nor should leaders less than 8 in in diameter be used. It is not considered good commercial practice to specify diameters except in whole inches, although there is no real reason for not using half inches if necessary. The tops of leaders should be at the same elevation as they leave the furnace bonnet, and from this point there should be a uniform up-grade of 1 in per foot of run in all cases. Leaders over 12 ft in length are to be avoided or receive very special attention.

The leader capacity curves already described under Leader Sizes are based on stack-leader ratios of approximately 70%, but frequently the designer will find it desirable or necessary to use larger or smaller ratios and hence Figs. 60

* See the Standard Code Regulating the Installation of Warm-Air Heating Systems in Residences.

and 61 showing the performance of a great variety of stack-leader combinations for 8-in and 10-in leaders have been given for second-floor systems.

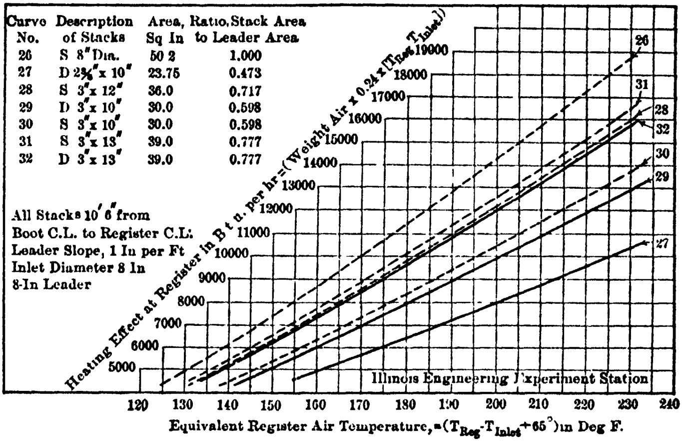

Fig. 60. Heating Effect at Registers for Various Stacks with 8-in Leader

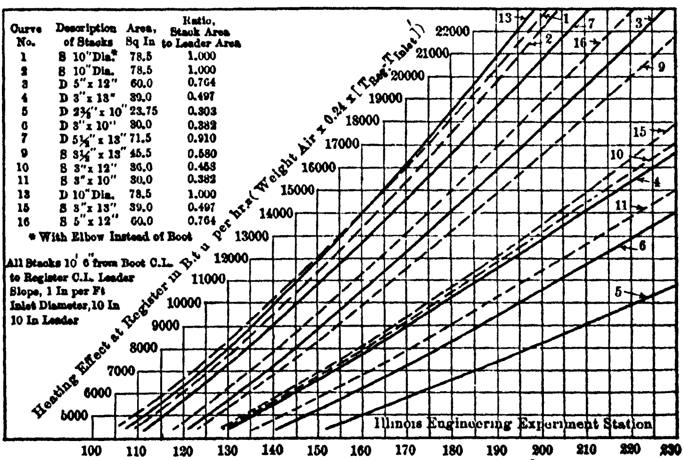

Fig. 61. Heating Effect at Registers for Various Stacks with 10-in Leader

The leaders may be laid off (Fig. 58) by dividing up the circumference of the bonnet into areas proportional to the amount of air to be distributed by each leader, and then connecting collar and leader radially to furnace-cap,

making one or more elbows in the leader, if necessary, to connect with stack. Another method is to run practically all leaders direct from the furnace to the foot of stack (Fig. 59) and cut the collars in on the angles at which they intersect the casing. The former method is recommended, and requires less skill and special fitting of leaders in installation.

The basement heating plan (Fig. 68) for an actual installation is shown with radial leader connections to the bonnet.

(c) **Stack Sizes.** The wall pipe or stack for an upper floor should be made not less than 70% of the area of the leader. So long as the leader is short and straight, as was the case for Fig. 57, such a practice is probably justified since the loss in capacity occasioned by the smaller stack is not very serious for ratios above 70%. For leaders over 8 ft in length or for leaders which are not straight, the ratio of stack-area to leader-area should be greater than 70% in order to offset the greater temperature losses in the longer leader. In gravity circulating systems, this STACK-LEADER RATIO is a very important consideration. Specific data for a variety of cases are presented in Figs. 60 and 61, and the designer should check his stack-leader combinations with the nearest comparable case as shown in these figures. Any second-floor stack supplying heat to a room requiring 10 000 Btu per hour will need a 6-in studding space at a register air temperature not in excess of 175° F. The desirability of using uniformly high stack-leader ratios throughout the installation cannot be too strongly recommended, since if a uniform stack-leader ratio is not maintained the temperature losses for the smaller ratios will be excessive and the rooms served by them will be underheated. See Tables XXXVII and XXXVIII for commercial sizes of stacks.

(d) **Warm-Air Register Sizes** (Figs. 62 and 63). After the sizes and locations of all leaders and stacks have been determined, it is a simple matter to

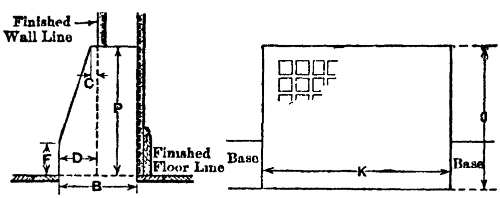

Fig. 62. Baseboard Stackhead and Register Dimensions (See Table XLI)

select suitable types and sizes of warm-air registers, from tables of commercial types of registers. See Tables XXXIX to XLI.

The registers used for discharging warm air into the rooms should have a FREE OR NET AREA not less than the area of the leader in the same run of piping. The free area should be at least 70% of the gross area of the register. No upper-floor register should be wider horizontally than the wall stack, and it should be placed either in the baseboard or side-wall, and not in the floor. First-floor registers may be of the baseboard or floor type with the former location preferred. No first-floor register should require a register-box more than 14 in wide, although it may be longer than 14 in.

All warm-air registers should be located in or close to inside partitions as attempts to run stacks in cold outside walls or extend long, first-floor leader runs to cold walls almost always result in failure. Registers should, of course, be located so as to interfere as little as possible with rugs, furniture, and

passageways, which means they must be kept out of the floor. Experimental data indicate that, in general, the BASEBOARD location gives better heating effects for both first- and second-floor registers, although the particular combinations of fittings used in entering the register-box has a marked effect on the relative merits of the two locations. The results of tests indicate that choice between floor and wall types of register combinations should favor that system which offers the least resistance due to elbows or angles.

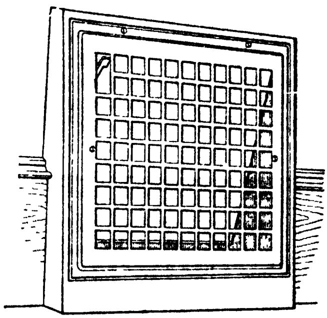

Fig. 63. Baseboard Register with Single Valve

NOTE: Baseboard register used on First Floor takes the supply from a flue 8⅝ in deep or 5 in deeper than the studding.

(e) **Air-Supply Duct Sizes** (Fig. 67). Ducts for recirculating air from the house or for bringing in outside air should be as short and direct as possible. The areas of such ducts should never be less than the combined areas of all warm-air leaders, and ducts of the recirculating type may be made even larger than the total leader-area. It is usually sufficient to base the size of either recirculating or outside-air ducts on leader-area, although it is also desirable to check this size against velocity of flow which should not exceed 4 ft per second in short straight ducts and 3 ft per second or less in long ducts or ducts with several turns. The air-volume and velocity should be based on density of air at 65° F.

The superior performance of the round duct using two 45° instead of two 90° elbows is very apparent, and the leader capacity curves (Fig. 57) used for designing a gravity furnace system apply to such an installation.

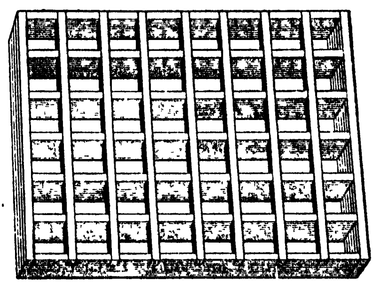

Fig. 64. Wooden Cold-Air Face.—Floor Type

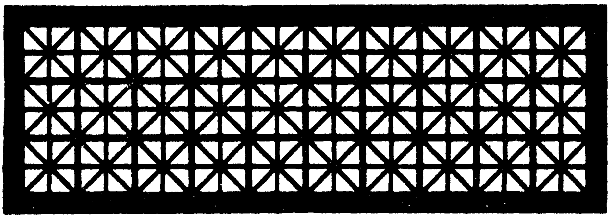
Outside-air duct connections, if used, should be made to a window-frame the full area of duct and such window should be in a wall exposed to prevailing winter winds. The inside type of recirculating duct or ducts is always preferred for residence installations.

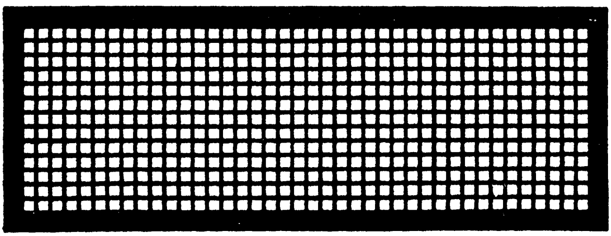
(f) **Recirculating Register Sizes.** (Fig. 64, Table XLII.) The number and location of recirculating registers, as in the case of the recirculating ducts, must be considered in arriving at the sizes, although it is usually quite sufficient to make the free area of such registers equal to the duct-area. If a single recirculating connection is used, the register through which the air in the building is returned to the furnace should always be placed in a central position in the first floor, usually in the main hall if one exists. Air from the upper floors must have free access to this register through the stairway of the building. Sometimes more than one return-air register is found desirable, and such multiple

returns are often justified provided the total cross-sectional area of ducts and registers is increased materially over that for a single, return-duct system.

(g) **Furnace Size.** The furnace should be selected on the basis of warm-air operation so that it will never be necessary to supply air at the register faces at a temperature above 175° F. even on the very coldest day. Furnaces at present are rated on the basis of the number of square inches of basement leader-pipe which they will supply. This rated area should always be approximately equal to the sum of the areas of all the warm-air leaders to which the furnace is connected. It is therefore possible simply to add up the areas of the basement leader-pipes as determined by the factors taken from Fig. 57 at a register air temperature of 175° F., and then select a furnace having not less than this rated capacity in square inches of leader-pipe. (See Tables



Grecian 3 In.—47% Open Area



Square—55% Open Area

Fig. 65. Two Types of Metal Grills

XLIV and XLV.) It is unwise to increase this value by taking the next size larger furnace.

Selecting a furnace on the basis of LEADER-PIPE AREA alone is a quick and simple procedure, but most designers will insist on a method for further checking the selection. In the investigation of furnace performance at the University of Illinois, it was found that, for any given type of furnace having a constant heating surface-grate surface ratio, the grate-area required to provide a given heating capacity depends on several factors. First, the AIR TEMPERATURE at the register for which the plant has been designed must be determined. Usually this temperature is taken as 175° F. Second, the COMBUSTION-RATE must always correspond with the register air temperature.

For 175° register warm-air temperature the combustion rate is 7.5 lb of coal per sq ft of grate per hour. The third factor is the EFFICIENCY, which is

about 57.5% and must correspond to the first two factors. The fourth factor is the HEAT VALUE per pound of fuel burned, which was 12 790 Btu.

Let H_b = heat available at bonnet in Btu per hour;
H_h = actual total heat loss from house in Btu per hour;
1.33 = provision for a 33% heat-loss between furnace bonnet and register (in some cases, under very favorable conditions this value may be 1.25);
G = grate-area in square feet bottom firepot area;
E = efficiency of the furnace (0.55 to 0.62);
F = fuel value of the coal in Btu per pound (usual assumption 12 000 to 13 000);
C = pounds of coal burned per square foot of grate surface per hour (usual assumption 5 5 to 7 5).

Then
$$H_b = 1.33\, H_h = G \times C \times E \times F \tag{7}$$

The equation may be written to express GRATE-AREA direct as,

$$G = \frac{1.33\, H_h}{C \times E \times F} \tag{8}$$

Assuming $E = 0.575$, $F = 12\,800$ and $C = 7.5$, then
$$G = H_h \div 41\,500 \tag{9}$$

Having found the desired grate-area, it is necessary to select a commercial furnace having the corresponding grate and casing diameters as given by manufacturers' data. The leader-area as calculated should also be again checked against the makers' data.

Suppose it is desired to select a furnace to deliver air to the rooms at a register temperature approximating 160° rather than 175° F., the relation is —combustion-rate 5.5 lb, register air temperature 160° F., and efficiency of the furnace 62%.

(h) Chimney Sizes. The area and internal dimensions of the chimney may be taken from Table XVIII.

Rating a Warm-Air Furnace. It is also possible on the basis of the performance data for leaders and stacks, and Equations (1) and (4), to set up a RATING EQUATION OF FORMULA for any common type of warm-air furnace. Simply divide the heat available at the registers by the average leader carrying-capacity based on a two-story installation.

Thus, from Fig. 57, at 175° F. register air temperature the average leader capacity per square inch is $(104 + 172) \div 2 = 138$ Btu. Hence the rating of a furnace (A) in square inches of leader pipe is, under the conditions itemized below (see Equation (7) for literal values):

$$A = \frac{0.75\, H_b}{138} = \frac{0.75\, G \times C \times E \times F}{138}\,[1 + 0.02\,(R - 20)] \tag{10}$$

and substituting the same values for C, E and F as in Equation (7) for a register air temperature of 175° F., the rating of a furnace in square inches of leader pipe is:

$$A = 300 \times G\,[1 + 0.02\,(R - 20)] \tag{11}$$

Note that $300 = \dfrac{7.5 \times 0.575 \times 12\,800 \times 0.75}{138}$, and in case G is in square inches instead of square feet then

$$A = 2.08\, G\,[1 + 0.02\,(R - 20)] \tag{12}$$

Equations (11) and (12) apply to commercial furnaces when operating under the following conditions:

(1) Fuel, stove-size anthracite coal of 12 800 Btu heat value per pound as fired.

(2) The chimney, 12 in in diameter and 35 ft high, and ample to create the draft necessary to burn 7.5 lb coal per square foot of grate per hour. On some tests, this chimney supplied sufficient intensity of draft to burn over 13 lb of coal per square foot of grate per hour.

(3) The cold-air duct, of the recirculating type with large flat shoe and a single register at first-floor level.

(4) Casing, of best diameter for each furnace tested, with a black iron liner and 1-in air space. The bonnet, conical, without radiation shield.

(5) Leaders, stacks, and registers supply air to three floor-levels.

Table XXXVI.—Sizes of Commercial Round Pipe-Leaders and Ducts, 2-Piece 30° and 45° Angles, 3-Piece 60° Angles, and 4-Piece 90° Angles, of IC, and IX Tin and 26 and 28 United States Standard Gauge, Diameter, Inches

5	6	7	8	9	10	12	14	16	18	20	22	24	26	28	30	32	34	36

Table XXXVIII. Sizes of Double-Wall Pipe and Fittings of IC and IX Tin, Inches

Inside..	2⅝×10	3 ×10	2⅝×12	3 ×12
Outside.......	3¼×10⅝	3⅝×10⅝	3¼×12⅝	3⅝×12⅝
Size of collar in boots.....	8–9	8–9	8–9	8–9–10
Inside..	3 ×13	4⅜×13	4⅜×14	.....
Outside.....	3⅝×12⅝	5 ×13⅝	5 ×14⅝	....
Size of collar in boots......	9–10	10–12	10–12	....

Note. The commercial wall pipe sizes are in general much too small to develop the full carrying capacities of leaders to fit the size of collar in boots. In only a few cases is the wall pipe area equal to 75% of the collar or leader-area.

Standard Register Sizes. The commercial sizes of floor, wall and ceiling registers range from 4 in × 6 in to 38 in × 42 in, varying by even inches with a few odd sizes.

In order to simplify and standardize the selection of warm-air registers for the average residence installation, a Joint Committee on Standardization of Warm Air Registers, composed of register manufacturers, made the following recommendation at a meeting on September 4, 1923.

Table XXXIX. Standard Register Sizes for Warm-Air Furnace Heating, Inches

Leader pipe diameter	Register size	Stack head, outside dimensions	Base extension
First-floor baseboard registers*			
8	8×10	6⅛×10⅝	2¼
9	9×12	6⅛×12⅝	2¼
10	10×12	7⅛×12⅝	3¼
12	11×13	9⅛×13⅝	5¼
12	12×14	9⅛×14⅝	5¼
Second-floor baseboard registers			
8	8×10		Min 1 in, max 1¼ in
8	8×10	.	Min 1 in, max. 1¼ in
9	9×12		Min 1 in, max 1¼ in
Floor registers			
8	8×10		.
9	9×12	.	. . . . .
10	10×12		. . . . . .
12	12×14		. . . . .
14	14×18		. . . .
16	16×22		. . . .

* No recommendation for 14-in diameter pipe Bottom of register from 2 to 2¼ in above finished floor.

The use of a FLOOR REGISTER may be permitted in an entrance hall for drying shoes and garments, but it is most unsanitary and cannot fail to collect dirt and filth of all kinds, and is subject to the further objection that its use frequently requires the cutting of carpets. In case such registers are used, however, suitable register-boxes must be provided, and are preferably constructed with double walls and tapered from the round collar to the top of the rectangular box.

Table XL. Dimensions of Register-Boxes, Inches

6×8	9×12	12×14	14×18	16×18	16×30	18×30	20×30	24×27	27×38	36×36
8×10	10×12	12×15	14×20	16×20	18×21	20×24	21×29	24×30	30×30	38×42
8×12	10×14	14×16	14×30	16×24	18×24	20×26	24×24	27×27	30×36	..

Registers with a high percentage of FREE AREA are desirable, since smaller commercial units may be used, and provide the same free area as larger sizes. The frictional losses through the register grilles are an insignificant item in any gravity circulating warm-air furnace plant, provided the registers have a free area above 70% of gross area and not less than leader or return-duct area. All registers on the warm-air side of the system should have SHUT-OFF VALVES or LOUVERS for controlling air-flow.

Warm-air registers may be placed in the floor, but preferably they should be located in or against inside partitions, for first-floor rooms. By using the modern BASEBOARD REGISTER it is usually possible to secure the required capacity without resorting to floor registers. These baseboard registers can be connected to a flue from 3 to 4½ in deeper (Table XLI) than the studding. This has been accomplished by making the special baseboard register so that it projects 2 in into the room at the floor line, necessitating the floor being cut out, and also utilizing the space of about 1 in occupied by the lath and plaster, or a total increase in depth of flue of about 3 in. For special conditions where ordinary baseboard register cannot be set in the partition, an OUT-O-WALL BASEBOARD TYPE may be used successfully. For upper-floor rooms registers should be placed in inside partition walls, using BASEBOARD or CONVEX REGISTERS for shallow stacks. As a general rule warm-air registers should be so placed as to shorten leader and stack connections as much as possible.

* In the case of first-floor baseboard registers, "stack-area" is in reality throat-area.

† Baseboard registers in all rooms except E. and W. dormitories and bath with side wall type.

Total heat loss with sun-porch, 141 805 Btu, with dining-room = 6 615 Btu, and sun-porch = 26 450 Btu.

Size of furnace is based on equations (1) and (3) in section on Furnace Size and is calculated as follows:

$$G = \frac{1.33H}{C \times E \times F} = \frac{1.33 \times 118\,200}{7.5 \times 0.575 \times 12\,790} = 2.85 \text{ sq ft}$$

G in square inches = 144 × 2.85 = 411, or nearest diameter = 23 in at 415 sq in

(1) The heat loss for each room was calculated for a mean breathing-level temperature of 70° F. inside in all heated rooms, and for outside weather conditions of 0° F. and a wind movement of 15 miles per hour. The sun-porch and an unequipped bath on the third floor were not heated, and the temperature of attic spaces was assumed as 35° F. In all respects, the residence is of standard frame dwelling construction, with the single exception of the studding, which is 2 in by 6 in instead of the usual 2 in by 4 in This, according to the commonly accepted theory of heat transmission of walls, operates to increase the wall heat-loss, but permits the use of larger wall stacks than could be used in 2 by 4-in construction. The wall section is as follows: weather boarding, building paper, ship-lap siding on 2 by 6-in studding, lath, and plaster with rough sand finish. The coefficient of heat-transmission for this wall section is 0.20 Btu per sq ft per hour per 1° F., at a wind velocity of 15 miles per hour. The walls were not insulated, nor was weather stripping used at the windows and doors. Interlocking copper shingles were used on the roof.

(2) The calculated areas of leaders were found by dividing the heat-loss from each room by the heat-carrying capacity of each square inch of leader, for which, at a register air temperature of 175° F., the values are derived from Fig. 54.

1 sq in of leader to first floor = 111 Btu per hour
1 sq in of leader to second floor = 167 Btu per hour
1 sq in of leader to third floor = 200 Btu per hour

Since these values apply only when wall stack areas are about 75% of leader-areas, the calculated stack-areas were found by multiplying leader-areas by 0.75.

(3) The net internal volumes of all heated rooms were totaled as a basis for making an estimate of the number of recirculations required per hour as shown in the following calculation.

The weight of air (W) to be circulated per hour must be sufficient to supply the heat-loss (H) when the air temperature drops from 175° to 70° F.

$$H = W \times 0.24 \times (175 - 70) \quad \text{or} \quad W = 4\,690 \text{ lb per hour}$$

and the air volume (Q) at 70° F., corresponding to this weight, is

$$Q = \frac{W}{0.075} = \frac{4\,690}{0.075} = 62\,600 \text{ cu ft per hour}$$

which gives as the number of recirculations (N) in zero weather:

$$N = \frac{62\,600}{16\,596} = 3.75$$

(4) The actual leader-areas and diameters were selected as nearly as possible in accordance with the calculated areas, adjusting somewhat for long and short runs, and using pipe-diameters in whole inches. The only exceptions made to this precedure were in the case of the leader-pipe to the combined halls and to the east bedroom, second story. The total hall requirements call for 155 sq in, whereas only 113 sq in or a 12-in diameter leader was installed. The location of the recirculating register in the first-story hall floor was regarded as justification for this reduction. In the case of the east bed oom, the short direct run taken off near the furnace front was regarded as very favorable, and, as an experiment, the leader size was reduced from 12 in to 10 in. The results were quite satisfactory in this particular installation, but such a large reduction would not be advisable except under very special conditions. No leader less than 8 in in diameter nor more than 12 in in diameter was used.

(5) The actual stack or throat-areas were selected to agree as nearly as practicable with the calculated areas, but at the same time careful consideration was given to the installa-

tion conditions affecting each stack leader system. Stack-areas were kept in excess of 75% of leader-areas unless especially favorable conditions existed. This was not done in the case of the third-story dormitories, which have a stack leader ratio of 0.60 instead of 0.75, and these rooms are somewhat underheated as a result. These stacks should have been made 3 in × 12 in or possibly 3 in × 13 in, instead of 3 in × 10 in.

(6) The warm-air registers were so selected that in each case the free area through the grilles would be not less than the leader pipe area on the same run. Registers of the baseboard type having free areas of at least 70% of the gross or commercial areas were chosen and no register had either dimension more than 14 in. Three side-wall registers with free areas slightly under 70% of gross areas were used in the two third-story dormitories and the bathroom on the second floor.

Table XLVIII. Cold-Air Return Duct Size

Location	(1) Free area of grilles *	(2) Area of ducts	(3) Area of shoes
Single return:			
Center of front hall..	800 sq in	854 sq in	728 sq in
(Dimensions)...	(36 in × 36 in)	(33 in diameter)	(14 in × 52 in)

* The free area of the grille is 61.5% of the total area

(1) The total cross-sectional area of the recirculating duct system was made not less than the total leader-area of 832.5 sq in. A 36 × 36-in grill (free area at 61.5% = 800 sq in) was selected for the front hall, although slightly under size. The small increase in friction to air-flow through the grille was compensated for by the short direct duct.

(2) A round duct with well-tapered connections at register-box and furnace-shoe was selected with total area slightly in excess of total leader-area.

(3) Shoe-areas are limited to an extent by two items: the height of grate above top of base ring and, in the case of the single-return, the diameter of the casing. In the present case, the former dimension is 12 in and the latter 52 in. Shoes wider than casings are unsightly and expensive, hence for the single-return system a compromise was made, and a 14 by 52-in shoe selected. This shoe had 12.5% less area than the total leader area.

Central Fan Heating

General Features. The mechanical indirect method of heating, commonly known as the CENTRAL FAN SYSTEM, particularly adapted to the warming and ventilating of large structures, is made up of three units: (1) A HEATER constructed of pipes, tubes, or cast-iron sections, through which steam, hot water or hot gas may be passed. (2) A FAN OR BLOWER to circulate air over the heater surfaces, the air acting as a heat carrier or medium of heat-transfer. (3) A SYSTEM OF DUCTS OR PIPES to convey the heated air from the heater to points where heat may be required. When the heater is located between the fan and main duct, the combination is termed BLOW THROUGH, and when the fan is installed between the heater and the duct, the arrangement is known as DRAW THROUGH. These two arrangements are shown in Fig. 70. The DRAW-THROUGH combination is more often used for shop and factory installations where compactness is desirable, the BLOW-THROUGH combination being used principally for HOT-AND-COLD systems as installed in schools and public buildings.

Advantages of the Blower or Hot-Blast System. The advantages of the blower or hot-blast system over those of direct radiation, briefly summarized, are:

(1) When ventilation is a requirement in order to maintain a healthful atmosphere, this method affords a positive means of accomplishing this

particularly desirable result, which is entirely independent of the changing climatic conditions.

(2) When a standard humidity of the air is to be maintained, a feature which is becoming to be more generally recognized as desirable in any heating-and-ventilating installation, and quite essential to the successful manufacture of some materials, the humidifying-apparatus may readily be made an integral part of the system.

(3) A much smaller amount of radiating-surface is required to perform an equal heating-duty, with a consequent reduction in the number of steam-tight joints, unions and valves to keep in repair.

(4) The air-leakage being mostly outward, the building will in general be freer from drafts and more uniformly heated. If the air is simply recirculated, no fresh air being taken into the heating system from the outside, the above statement does not apply. The pressure of the air in the building, even when all of the air is taken into the heating system from the outside, is comparatively feeble, and some air will enter by infiltration through the window and door-cracks on the windward side of the building, although the statement is often made that the leakage being all outward, prevents the infiltration of cold air from the outside.

(5) This system is more easily regulated, and readily responds to changing outside temperatures.

(6) The air entering for ventilation may be conveniently cooled in summer, either by the circulation through the heater of cold water or of brine previously cooled by mechanical refrigeration.

(7) Simply running the fan will in itself greatly relieve the oppressiveness in hot sultry weather, and when cold water is circulated through the coils the difference is very noticeable.

Typical Arrangements. When ventilation is not a requirement, or when it is relatively unimportant, as is frequently the case in shop or factory-heating where the number of persons vitiating the air is small compared with the cubical contents of the building, the air may be simply RECIRCULATED, sufficient fresh air for ventilation being supplied by infiltration. The amount of heat to be supplied the heater in this case is the same as would be required for a direct-radiation installation. When ventilation is a requirement to be met a COLD-AIR INTAKE is provided. Since the amount of air necessary for heating is generally in excess of the amount required for ventilation considerable economy may be effected by recirculating a portion of the air. In this case only sufficient fresh air is drawn into the system from the outside to meet the ventilation requirement and the remainder of the air necessary for heating, is recirculated. This may be readily effected by an arrangement of ducts and dampers on the suction-side of the fan. If the fresh air introduced is to be washed or conditioned the washer or humidifier and tempering-coil may be added between the inlet for the recirculated air and the fresh-air intake.

Amount of Air to be Circulated for Heating. The weight of air to be circulated per hour for heating a room or building is found by dividing the heat-loss (H) by the amounts of heat given up by 1 lb of air in cooling from the temperature at the duct-outlets to the mean room-temperature.

Let H = heat-loss of room, Btu per hr;
M = weight of air to be introduced in room per hour;
t = mean inside temperature;
t_d = temperature of air leaving duct-outlets.

Then $$M = H/[0.24\,(t_d - t)]$$

The temperature t_d depends upon the temperature of the air entering the heater, the velocity through the clear area, the amount of heating-surface and the temperature of the steam. This temperature in practice ordinarily ranges from 125° to 150° F. and may be readily determined for any specified condition by the data given later under Hot-Blast Heaters. The temperature of the air leaving the duct-outlets for ordinary installations, when the ducts are not run underground or in outside walls, may be assumed to be the same as the temperature (t_2) of the air leaving the heater. Any loss in temperature in this case goes toward heating the building and is therefore not a direct loss. If, however, the ducts are run underground or in outside walls, a considerable loss in temperature may occur, which is a direct loss, and must be provided for by INCREASING THE TEMPERATURE OF THE AIR LEAVING THE HEATER by an amount equal to the estimated temperature-drop in the ducts.

Temperature of Air Entering Heater.

Let t_1 = temperature of air entering heater;
t_0 = outside temperature;
t = mean inside temperature;
t_2 = temperature of air leaving heater;

(*a*) When the air is all recirculated, $t_1 = t$;
(*b*) When fresh air only is circulated, $t_1 = t_0$;
(*c*) When a portion of the air is recirculated the resulting temperature of the mixture of fresh and recirculated air may be found by the METHOD OF MIXTURES.

Let M_v = weight of fresh air, pounds required per hour for ventilation (30 cu ft per min per person);
= 0.075 × 1 800 × number of persons (usual requirements);
M_r = weight of air that may be recirculated;
$M = M_v + M_r$;
$H = 0\ 24\ (M_v + M_r)\ (t_d - t)$.

Having assumed or fixed the value of t_d, the only unknown quantity is M_r.

$$M_r = H/[0.24\ (t_d - t)] - M_v$$

The temperature t_1 may then be found as follows:

$$M_v \times (t_0 + 460) = A$$
$$M_r \times (t + 460) = B$$
$$(M_v + M_r)\ (t_1 + 460) = A + B$$

or
$$t_1 = (A + B)/(M_v + M_r) - 460$$

Example. The heat-loss H for a certain factory-building is 70 600 Btu per hr. The number of men employed is 50. Mean inside temperature t = 65° F. Outside temperature t_0 = 0° F. Ventilation is to provided at the rate of 1 800 cu ft of fresh air per hour per person. Assumed temperature of air leaving duct-outlets is 135° F.

Solution. M_v = 0.0075 × 1 800 × 50 = 6 750 lb per hr fresh air for ventilation. The weight of air that may be be recirculated is

$$M_r = 706\ 000/[0.24\ (135 - 65)] - 6\ 750 = 35\ 273 \text{ lb per hr}$$

The temperature of the air entering the heater will be:

$$6\ 750 \times (\ 0 + 460) = 3\ 105\ 000$$
$$35\ 273 \times (65 + 460) = 18\ 516\ 750$$

$$t_1 = (21\ 621\ 750/42\ 023) - 460 = 55° \text{ F.}$$

If FRESH AIR ONLY is to be used, as in school-house and public-building heating, the weight of air to be circulated is determined directly by the ventilation requirement.

Then $M = M_v = H/[0.24\,(t_d - t)]$, or $t_d = (H + 0.24\,M_v t)/0.24\,M_v$

Temperature of Air at Duct-Outlets. When heating, by the hot-blast system, a building containing a number of rooms having different heat-losses and ventilation requirements, it is obviously impossible to maintain the desired temperature by controlling the temperature (t_2) of the air leaving the heater at one point. The temperature t_d of the air leaving the duct-outlets will ordinarily be different for each room in the building, as shown in the following example. This result is accomplished by the double plenum-chamber system described later.

Example. Let it be required to determine the temperature of the entering air (t_d) to offset the heat-loss and provide ventilation for the several rooms as given in Table XLIX. Inside temperature (t) to be maintained is 70°.

Table XLIX. Data for Example

Room-number	Number of occupants, n	Ventilation		Heat-loss, H	Temperature of entering air, t_d (see formula)
		Cubic feet per hour, at 70°, 1 800 × n	Weight per hour, M_v		
A-1	50	90 000	6 750	32 000	89 5
A-2	53	95 400	7 125	21 000	82.2
Hal'	. .... .	30 000	2 250	4 000	77.4

Temperature of Air Leaving Heater. If all of the air is first warmed by the TEMPERING-COIL to 70° F., and a mixture of approximately $(1 - x)$ parts of tempered air and x parts of hot air is to be used, then the required temperature of the hot air leaving the heater may be determined, for any particular case, by the METHOD OF MIXTURES previously given; or, assuming this temperature, the proportions of hot and tempered air may be determined.

Example. Required the temperature of the hot air (t_h) leaving the heater for room A-2 (Table XLIX), if the mixture entering the room is made up of one half tempered air at 70° and one half hot air. The total weight of air entering the room is 7 125 lb per hr, or 3 562.5 lb of tempered air and 3 562.5 lb of hot air.

Solution. $3\,562.5 \times (70 + 460) + 3\,562.5 \times (t_h + 160) = 7\,125 \times (82.2 + 460)$. Hence $t_h = 94$.

Assuming a temperature of $t_h = 120°$, it is required to determine the relative proportions, by weight, of the mixture required.

Let x = parts of hot air in mixture. Then $(1 - x)$ = parts of tempered air.

$$x\,(120 + 460) + (1 - x) \times (70 + 460) = (82.2 + 460)$$

Then

$$x = 0.244 \quad \text{and} \quad (1 - x) = 0.756$$

Air Supplied for Ventilating Purposes Only. Split System. A combination to direct radiation, to offset the heat-loss H, and a hot-blast system, to supply the fresh air needed for ventilation, termed a SPLIT SYSTEM, is sometimes

installed. In this case it is customary to install a heater of sufficient capacity to warm the air for ventilation to about 80°. The heater used for this purpose is made three sections deep and is termed a TEMPERING-COIL.

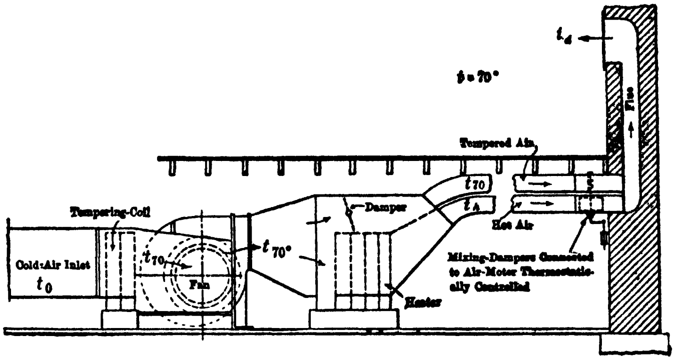

Fig. 69. Double-duct System

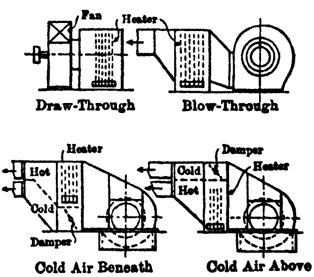

Fig. 70. Types of Heater-jackets

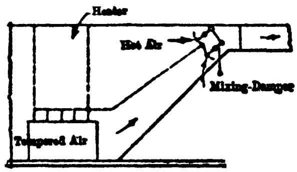

Fig. 71. Single-duct System

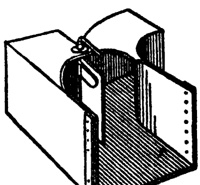

Fig. 72. Deflecting-damper for Branch-duct

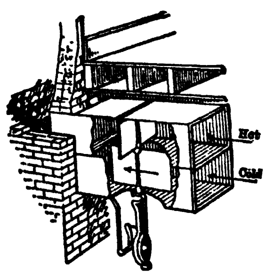

Fig. 73. Thermostatically-controlled Mixing-damper

Figs. 69 to 73. Details of Ducts for Hot-and-cold Heating Systems

Hot-and-Cold Systems. In order to accomplish the results required in the preceding example, the so-called HOT-AND-COLD SYSTEM or DOUBLE-PLENUM-CHAMBER SYSTEM is used. All of the air drawn into the system from the outside is first passed through a TEMPERING-COIL, which is designed to heat the

air to approximately 70°. A portion of the tempered air is then passed through a heater and raised to 125° to 150°. Then if varying proportions of the hot and tempered air are correctly mixed the resulting temperature (t_d) is readily controlled without varying the quantity of air discharged, which evidently must remain constant on account of the ventilation requirement. There are two methods of distribution used, as shown in Figs. 69 and 71. Referring to Fig. 71 it is seen that the hot and tempered air meet at the end of the plenum-chamber at the entrance to the ducts, and the temperature of the mixture is controlled by the MIXING-DAMPERS, which may either be hand-operated or placed under automatic thermostatic control. It will be observed that the plenum-chamber is divided, and that each duct serving a room has its own independent set of mixing-dampers. This method of distribution is known as the SINGLE-DUCT SYSTEM and is frequently employed where the installation of the DOUBLE-DUCT SYSTEM, as described below, is not feasible or is undesirable. Fig. 69 shows a double set of ducts run from the plenum-chamber to the base of each vertical flue, one carrying the hot air and the other the tempered air, the mixing being done at the base of the flue as shown. The mixing dampers (Fig. 73) may be controlled by hand by means of a chain carried up the flue and run into the room at a point several feet above the floor-line, or placed under automatic thermostatic control through the medium of a compressed-air-operated damper.

Hot-Blast Indirect Heaters

Copper-Tube Heaters. (Fig 74.) There are a number of spirally wound extended-surface copper-tube heaters available for hot-blast installations,

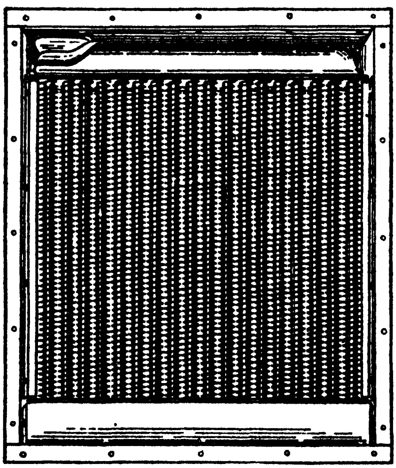

Fig. 74. Aerofin Low-pressure Blast Heater

as for example AEROFIN, ARCO BLAST (Am. Rad. Co.) and SUPERFIN (York Heating and Ventilating Corp.). Fig. 74 shows the low-pressure type as manufactured by the Aerofin Corp.

AEROFIN is made up of straight seamless copper or brass tubing about which

is wound a thin narrow helical extended surface, also of copper or brass made metallically integral with the tube by means of a mechanically effected solder bath. The helical extended surface is applied to the tubes by means of a machine which automatically corrugates the inner edge of the metal ribbon, and winds the ribbon uniformly about the tube, so that the pitch of the helix is uniform and the extended surface is at right-angles to the tube. As the metal ribbon is wound about the tube the machine treats the surfaces with acid and applies the molten solder while the tube and ribbon are held firmly in position. The solder is flowed over the tube and the extended surface so that both are entirely covered, forming a permanent metallic unit which is extremely effective for the transmission of heat.

The finished tubes are then mechanically pressed into thin flexible tube plates of copper, brass, or other non-corrosive metal, all of the tubes being pressed into both top and bottom plates in one operation. The punched holes in the tube plates are slightly smaller than the tubes themselves, so that a strong and tight joint is effected when the tubes are forced into the plates. The tube plate, when punched, is also cupped, or dished, around each opening, and formed so that there is a deep collar about each tube when pressed into the plate. This construction not only provides a great contact area between the tube and the plate, but also renders the plate flexible at the point of juncture with the tube, thus compensating for any movement of the tube due to expansion or contraction.

The SHELT-METAL JACKET is an integral part for all types of copper-tube heaters. The complete assembled blast heater is made up of a number of units similar to Fig. 74. The manufacturers furnish performance tables similar to the Vento tables, appearing later in the text, giving the temperature rise of the air, condensation and friction based on various air velocities through the heater. Copper-tube type heaters for pressures of 25 lb per sq in and above are usually constructed without the header, the pipe coil being of the return-bend type.

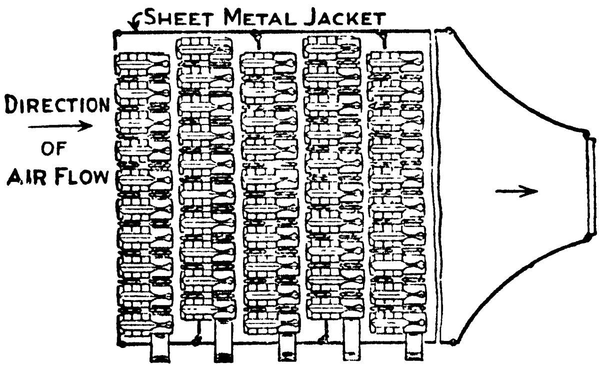

Fig. 75. Plan of the Assembly of a Vento Heater

Cast-Iron Indirect Heaters. Cast-iron sections for indirect heaters are often used, and Fig. 75 shows a cast-iron heating-unit or section, named Vento, manufactured by the American Radiator Company, which is quite widely used in this class of work. A STACK made up of several sections has a smaller

number of joints than a pipe-coil section of equal heating-surface. The deterioration of the cast-iron sectional type of heater is practically nothing except for the right-hand and left-hand hexagonal nipples connecting the units which go to make up a stack. There are three standard lengths of Vento heater-sections as indicated in Table L, which also includes other data required by the designer.

Table L. Vento Hot-Blast Heater-Data

Length of section in inches	Heating-surface, regular sections, in square feet	Free area in square feet, per section, inches on centers			Ratio, square feet, heating-surface to free area for 5 in on centers
		4⅝	5	5⅜	
40	10 75	0 52	0 62	0 72	17.34
50	13.50	0 65	0 77	0 91	17.53
60	16.00	0.78	0 92	1.08	17.39

Selection of Hot-Blast Heaters. General Conditions. In selecting the size of a heater for any particular service the choice is based on the final temperature desired and the FREE AREA required for a certain allowable velocity for Vento and the FACE AREA for Aerofin and similar type copper-tube heaters. That is, for any specified initial and final temperature desired, and a certain number of sections, a final temperature results when the velocity has been fixed in advance. Good practice limits the velocity to the values given by the following tables. High velocities are objectionable in public-building work on account of the resulting noise. The resistance through the heater increases in proportion to the square of the velocity, which adds to the power required to move the air as the velocity is increased, as will be noted later.

Rating of Hot-Blast Heaters. The RATING of an assembled heater of several sections or stacks is based on the TEMPERATURE-RISE of the air passing over the heating-surface for certain velocities through the free or unobstructed area of the heater-face for Vento and face area for Aerofin and Superfin. The VELOCITY is based on the volume of air at an assumed temperature of 70° for convenience in rating.

Let M = weight of air to be circulated through heater per hour;
0.075 = density of air at 70°;
A = either free area or face area of heater in square feet;
V = velocity of air in feet per minute through free area based on 70° temperature.

Then

$$A = M/(60 \times 0.075 \times V) = M/4.5\, V \text{ sq ft.}$$

The following tables will serve as guides in selecting the VELOCITY V and the NUMBER OF SECTIONS OR STACKS for various purposes.

Temperature-Rise. The TEMPERATURE-RISE of the air passing through hot-blast heaters of various types has been well established by experiment, the various manufacturers having published the results in the form of bulletins and catalogues.

Example. It is required to determine the size of a Vento hot-blast heater to supply the necessary heat for a public building, the calculated heat-loss of

which is $H = 1\ 420\ 000$ Btu per hr for 70° inside and 0° outside temperature. The temperature of the air entering the rooms, t_d, is to be approximately

Table LI. Allowable Velocities of Air through Free-Area Vento Heaters *

Referred to a temperature of 70° F.

Number of stacks deep, regular 5 in on centers	Public-building work, velocity in feet per minute	Factory work, velocity in feet per minute
4	1 000 to 1 500	1 200 to 1 600
5	1 000 to 1 300	1 200 to 1 600
6	1 000 to 1 200	1 200 to 1 600
7	900 to 1 100	1 200 to 1 500
8	800 to 1 000	1 200 to 1 400

* The allowable velocities for heaters rated on a based or *face area* will be approximately one-half the values given in table for Aerofin and Superfin heaters.

Table LII. Number of Stacks of Vento Ordinarily Required

Service	Number of sections or stacks	Number of rows of 1-in pipe
Public buildings, fresh air, exhaust-steam....	5	20
Industrial buildings, fresh air, 4-lb gauge .	6	24
Industrial buildings, fresh air, exhaust-steam. .	7	28
Industrial buildings, recirculation, 5-lb steam. .	5	20
Tempering-coils, fresh air, exhaust-steam .	3	12

120°. The steam-pressure is 5-lb gauge. The temperature of the air entering the heater is 0°.

Solution. First determine from Table LIII the number of stacks deep required for F.T. at 120° and entering air at 0°, using a velocity of 1 000 ft per min. This condition calls for a 5-stack-deep heater. Then determine the weight of the air to be circulated per hour.

$$M = H/[0.24\,(t_d - t)] = 1\ 420\ 000/[0.24\,(120 - 70)] = 118\ 333 \text{ lb}$$

The free area required is

$$A = 118\ 333/(4.5 \times 1\ 000) = 25.1 \text{ sq ft}$$

Referring to Table L and choosing a 60-in length of units, 5 in on centers, it is found that the free area per section is 0.92 sq ft. The number of sections required across the face of the heater is

$$A/0.92, \quad \text{or} \quad 25.1/0.92 = 27$$

The heating-surface per section is 16 sq ft. The total heating-surface is therefore

$$S = 5 \times 27 \times 16 = 2\,160 \text{ sq ft}$$

and the condensation per hour is

$$2\,160 \times 1.56 \text{ (Table LIII)} = 3\,370 \text{ lb}$$

to be supplied by the boiler, or by exhaust-steam, at 5-lb pressure.

Design of Air-Ducts

Pressure-Loss. The frictional resistance of air flowing through smooth sheet metal ducts, commonly termed PRESSURE-LOSS, measured in inches of water, for 70° air and for a length of duct equal to 100 ft, is given by the following formula:

$$h = 0.000136 \times (R/A) \times v^2$$

in which R is the perimeter of the duct in feet, A the area of duct in square feet, v the velocity of the air in feet per second, and h the pressure-loss measured in inches of water-column. For round ducts the above formula reduces to

$$h = 0.00055\, v^2/D$$

in which D is the diameter of the duct in feet.

The diagrams in Figs. 76 and 77 are based on this formula, from which the DIAMETER OF A ROUND DUCT for various velocities, and the PRESSURE-LOSS OR RESISTANCE for various quantities of air flowing, may be found without solving the above equation.

Example. What should be the size of a round duct required to convey 1 500 cu ft of air per minute with a velocity of 1 800 ft per min; and what is the pressure-loss per 100 ft of duct.

Solution. Locate 1 500 on the upper side of the pipe-diagram in Fig. 76, and pass horizontally downward until the 1 800-ft-velocity diagonal line is inter-

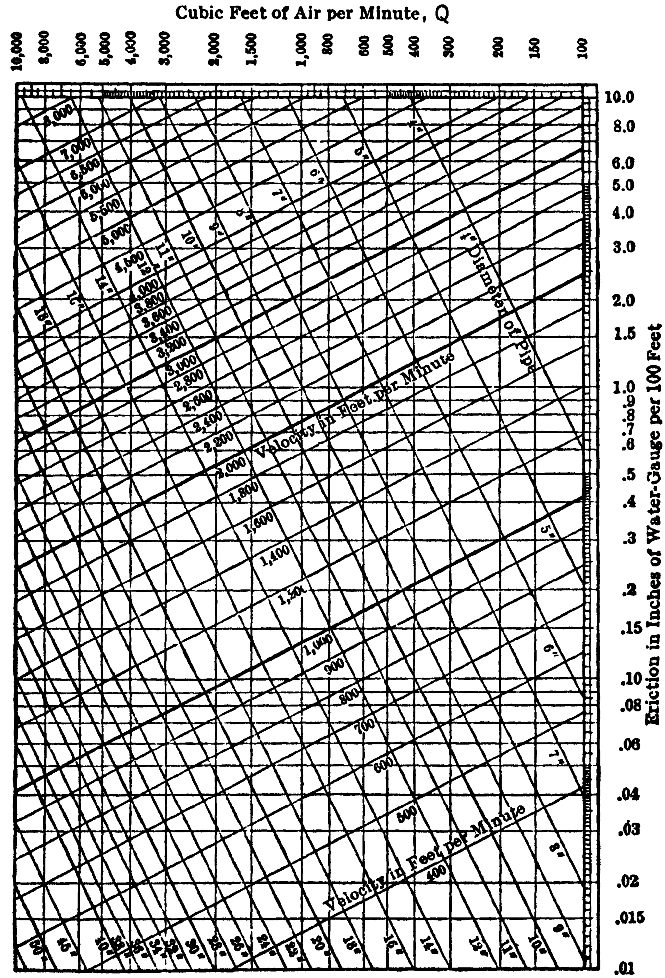

Fig. 76. Diagram of Friction-pressure Loss

sected. The duct which comes nearest to the required size has a diameter of 12 in. At this intersection pass to the right side to the base-line and read 0.48-in water-pressure loss.

Allowable Velocity of Air in Ducts and Flues. In order to limit the resistance or pressure-loss in the duct system the designer should, in general, keep

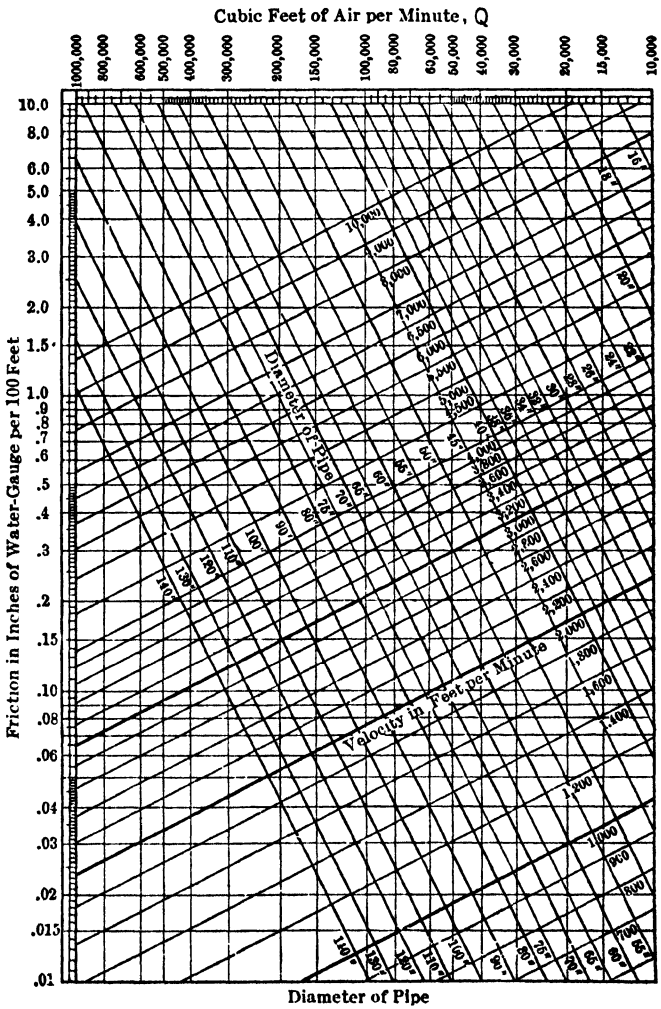

Fig. 77. Diagram of Friction-pressure Loss

the velocities within the limits stated in Table LIV. In public-building work the air should be delivered to a room at a velocity that will insure its movement to the desired points in the room without objectionable draft or noise in passing through the register-grills.

Table LIV. Allowable Velocities in Hot-Blast Systems

Types of buildings	Allowable velocity in feet per minute
Public buildings	
Through free area of wall-registers	400– 500
Through free area of floor-registers	200– 300
Vertical flues to registers	600– 750
Connections to base of flues	800–1 000
Main horizontal distributing ducts	1 500–2 500
Manufacturing plants	
In plants where the occupation is more or less sedentary and the employe sits all day feeding automatic machinery:	
Main ducts	1 200–1 500
Branches	600– 900
In plants where the employe stands all day, as in machine-shops, foundries, etc.:	
Main ducts	1 500–2 400
Branches	900–1 500

The velocity through the fan-outlet, under the ordinary conditions that obtain in heating work, varies from 1 500 to 2 500 ft per min.

Metal Ducts Construction. The accompanying Table LV gives the minimum thickness of metal for circular and rectangular air-ducts in heating and ventilating work.

Table LV. Guages of Galvanized Iron or Steel to be Used for Ducts, for Outside Air Intake

Heating and ventilating			
Round ducts diameter, in	Gauge	Rectangular ducts width, in	Gauge
6 to 10	26	Up to 12	26
11 to 29	24	13 to 30	24
30 to 39	22	31 to 60	22
40 to 49	20	61 to 118	20
50 and above	18	118 and above	18

Thus, a round duct 11 to 29-in diameter should be made of No. 24 gauge sheet steel, and a rectangular duct 31 to 60 in wide should be made of No. 22 gauge.

Pressure-Loss of Rectangular Ducts. The simplest method of determining this is to proportion the system for ROUND DUCTS throughout, and then transfer to RECTANGULAR SIZES giving equal pressure-losses (not equal areas) by means of Table LVI.

Table LVI. Round and Rectangular Ducts of Equal Pressure-Losses

Example. What is the width of a rectangular duct 6 in high equivalent to the pressure-loss for a duct 12 in in diameter? **Solution.** 22 in.

Table LVII. Friction Pressure-Loss of 90° Elbows

Radius of throat in diameters of pipe	¼	½	¾	1	1¼	1½	2	3	4	5
Number of diameters of straight pipe of equivalent pressure-loss . .	67	30	16	10	7.5	6	4 3	4.8	5.2	5.8

Example. A duct 12 in in diameter and 120 ft long contains two 90° elbows. The ratio of the radius of throat to pipe-diameter is 3. The amount of air flowing is 1 500 cu ft per min and the velocity 1 800 ft per min.

Solution. The total equivalent length of duct is

$$120 + (2 \times 4.8) = 129.6 \text{ ft}$$

The pressure-loss, from the diagram of Fig. 64, is 0.48 in per 100 ft. The loss is

$$0.48 \times (129.6/100) = 0.62 \text{ in of water}$$

The pressure-loss through register-grills may be taken at 0.023 in for a velocity of 400 ft per min through free area. The gross area of registers is twice the free area. The pressure-loss in standard air-washers for a velocity of 400 ft per min through the free area may be assumed to be 0.15 in of water. In the case of humidifiers, in which the spray is directed against the flow of air, a pressure-loss of 0.55 in of water may be assumed for preliminary estimates. The values assumed for this loss vary with different manufacturers. The pressure-loss through hot-blast heaters may be taken from Table LVIII.

Table LVIII. Friction of Air through Vento Heaters

Friction-loss, in inches of water, due to air passing through Vento stacks, based on free area of heater. Regular section. Standard 5-in spacing of loops. Air-temperature 70° F.

Velocity through free area in feet per minute	One stack	Two stacks	Three stacks	Four stacks	Five stacks	Six stacks	Seven stacks

1 800	0.190	0 354	0.518	0.683	0.848	1.012	1.177

Effect of Temperature on Pressure-Losses. The preceding data on pressure-losses in ducts, registers and heaters are based on an air-temperature of 70°. For other temperatures, the pressure-losses are to be multiplied by the ratio, density of air at actual temperature to density at 70°. These ratios are given in Table LIX. For heaters use the average temperature of the air passing through the heater.

Design of Duct Systems. There are two schemes used in PROPORTIONING AIR-DUCTS: (1) the velocity method, and (2) the method of equal friction pressure-loss per foot of length. The first method involves the fixing of the velocities (see Table LIV) in the various sections, and the gradual reduction of the

Table LIX. Ratios of Density of Air at Actual Temperature to Density at 70° F.

Temperature	Factor	Temperature	Factor
100	0 945	140	0.880
120	0.910	150	0 865
130	0.890	160	0 850

velocity from the beginning of duct to the point of discharge. In this case the pressure-loss is computed separately for each section having a different velocity and the various pressure-losses added together to obtain the total loss in pressure. The second method is used principally in the design of duct systems for factory-heating. The velocity in the outlet farthest from the fan is fixed and the area and diameter of this branch are determined by the volume of air to be delivered. The friction pressure-loss per 100 ft of a duct of this size is determined by the diagrams in Figs. 76 and 77. The remainder of the main duct is then proporticned for this same pressure-loss per 100 ft.

Example. The first method is illustrated in Fig. 78, showing a single-duct system. The risers are figured for a velocity of 600 ft per min, or 10 ft per sec;

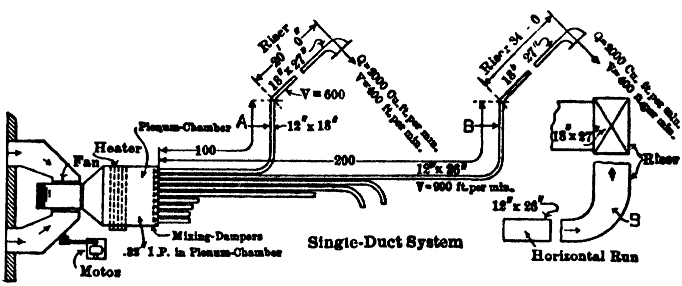

Fig. 78. Single-duct System

and 400 ft per min, or 6.6 ft per sec; through free area of register-grill. The velocity in the longest main, *B*, is 900 ft per min, the volume of air to be delivered 2 000 cu ft per min, and the temperature 120°.

Solution. The area of the riser required is

$$2\ 000/600 = 3\tfrac{1}{3} \text{ sq ft, or } 480 \text{ sq in}$$

An 18 by 27-in riser, giving 486 sq in area, is used. The area of main, *B*, is

$$2\ 000/900 = 2.22 \text{ sq ft, or } 320 \text{ sq in}$$

The size of the duct is 12 by 27 in. The diameter of a round duct for the same friction-loss for the riser, from Table LVI, is 24 in, and for the main, *B*, 19.5 in.

Referring to the diagram in Fig. 76, the pressure-loss for the riser is 0.032 in per 100 ft. For the main the pressure-loss is 0.09 in per 100 ft. The main has one elbow and the riser one elbow, and the ratio of radius at throat to diameter will be assumed to be 3, in both cases. The equivalent length of main, *B*, is therefore

$$200 + (4.8 \times 20/12) = 208 \text{ ft}$$

Double-inlet fans have approximately double the capacities of single-inlet fans and require for their operation, under the same conditions, approximately twice the power. The "per-cent opening" refers to the opening used for the rating given from the test-data.

*** C. F. M. denotes cubic feet per minute; R. P. M., revolutions per minute; and B. H. P., brake horse-power.**

and the pressure-loss is

$$0.09 \times (208/100) = 0.187 \text{ in}$$

The equivalent length of riser is

$$34 + (4.8 \times 24/12) = 44 \text{ ft}$$

and the pressure-loss is

$$0.032 \times (44/100) = 0.014 \text{ in}$$

The pressure-loss through the register-grill is 0.023 in. The total resistance of the duct system is therefore

$$0.0187 + 0.014 + 0.023 = 0.224 \text{ in}$$

Assuming that a five-section Vento heater is employed, with a velocity (figured through free area) of 1 200 ft per min, the pressure-loss through the heater is 0.376 in (Table LVIII). The total resistance against which the fan must operate is

$$0.224 \text{ in} + 0.376 \text{ in} = 0.60 \text{ in}$$

based on 70° air. Assuming the temperature of the air to be 120°, the resistance is

$$0.60 \times 0.91 \text{ (Table LIX)} = 0.55 \text{ in}$$

The second method of duct-design is illustrated by the example given under Application of Hot-Blast Heating Data.

Ventilating Fans

Steel-Plate Fan. The standard type of fan that was used for a number of years in hot-blast work is known as the STEEL-PLATE FAN, the construction of the wheel being shown in Fig. 79. As the name implies, the wheel and casing of this fan are constructed of steel plate and light structural sections, the wheel having eight to twelve blades, straight or slightly curved at the periphery, and in a direction opposite to the rotation. Steel-plate fans are designated by number, this number being the approximate height of the fan-casing in inches.

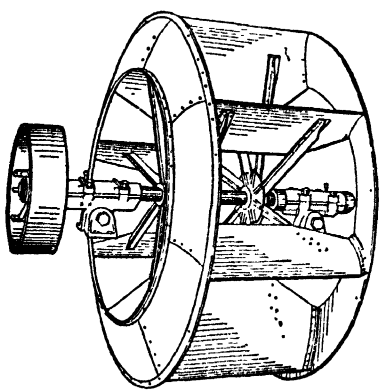

Fig. 79. Standard Steel-plate Fan-wheel

Multibladed Fan. The new type of fan wheel, known as the MULTIBLADE or TURBINE-TYPE IMPELLER, Fig. 80, is now used almost exclusively in the field of heating and ventilating, and on account of its higher efficiency, quieter running, and relatively smaller size for the same capacity than the steel-plate fan, has supplanted the latter. The higher efficiency is accounted for by the material reduction of the air-resistance or pressure-head loss by friction through the fan, due to the shorter blades and the larger inlet, which is of practically the same diameter as the wheel itself.

Rating of Fans. The volume of air at 70° which a fan will deliver (cubic feet per minute) varies with the resistance against which it operates. In order to choose a fan from Table LX, the resistance (static pressure) must first be determined by the duct-design, and after the size of the heater has been chosen and its resistance determined. The speed and brake horse-power required to drive the fan are also stated in the tables. The temperature of the air handled by the fan with DRAW-THROUGH apparatus is higher than 70°, except for a fan which is connected ahead of a tempering-coil, usually a two-section-deep heater. The tabulated speed, volume and brake horse-power to maintain the pressure must be multiplied by the factors given in Table LXI for temperatures other than 70°. The above factors in this table are the square roots of the ratios of the density of the air at 70° F. to its density at the temperature stated.

Table LXI. Factors for Speed, Volume and Brake Horse-power

Temperature in degrees Fahrenheit	Factors
0	0 932
100	1 028

130	1 055
140	1.064
150	1.073

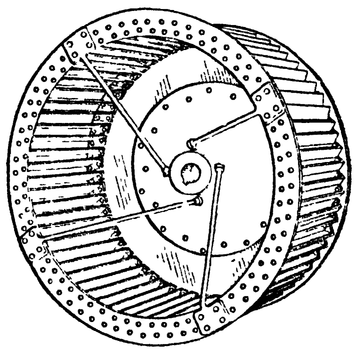

Fig. 80. Multiblade Wheel

Application of Hot-Blast Heating-Data to an Industrial Building

The Application of the Foregoing Data on hot-blast heating to an industrial building follows (see Fig. 81). The calculated heat-loss is 1 423 920 Btu per hr.

Conditions. Air recirculated and inside temperature maintained at 60°. Velocity of air through heater, from 1 000 to 1 200 ft per min. Velocity of air at last outlet in duct system, 1 275 ft per min. Temperature of air delivered by heater, 145°.

Weight of Air to be Circulated per Minute. This is

$$1\,423\,920/[0.24\,(145 - 60)\,160] = 1\,163 \text{ lb}$$

Size of Vento Heater. This condition, 60° initial and 145° final temperature, requires a heater five stacks deep (Table LIII), and a velocity of 1 000 ft per min through free area at a temperature of 70°. The volume of air per minute measured at 70°, to be handled by the heater and fan is

$$1\,163/0.075 = 15\,506 \text{ cu ft}$$

The FREE AREA required is:

$$15\,506/1\,000 = 15.5 \text{ sq ft}$$

Assuming a 60-in length of section with loops 5 in on centers, the free area per section is 0.92 sq ft (Table L). The number of sections per stack is

$$15.5/0.92 = 17$$

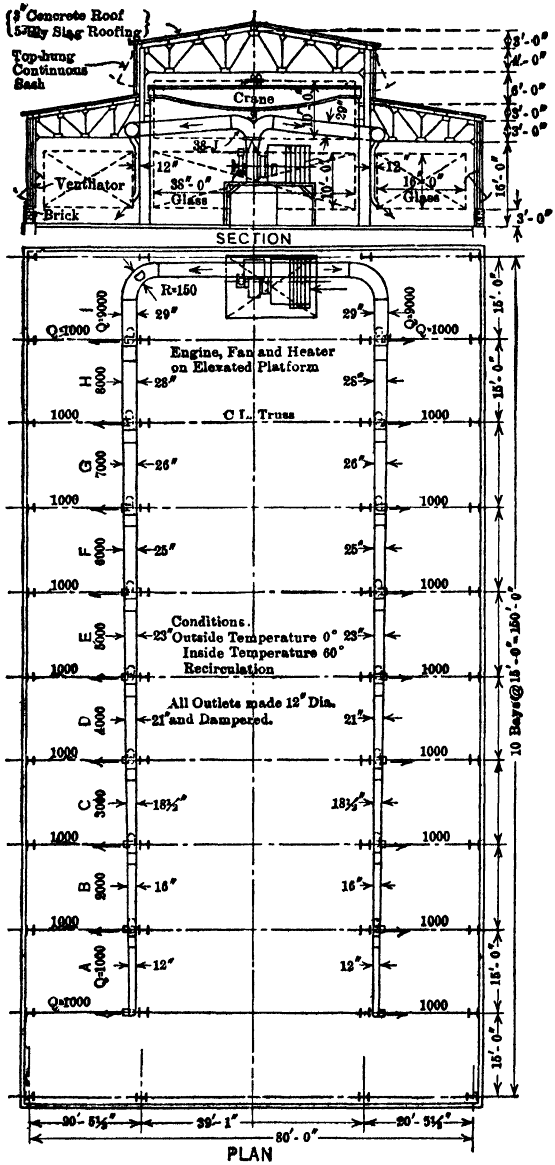

Fig. 81. Hot-blast Heating for a Factory Building. (See Example for Computations)

The total number of sections required is

$$5 \times 17 = 85$$

The total heating-surface is

$$85 \times 16 = 1\,360 \text{ sq ft}$$

Weight of Steam or Condensation per Hour. This is

$$1\,360 \times 1.09 \text{ (Table LIII)} = 1\,482 \text{ lb}$$

The equivalent amount of direct radiation is

$$1\,482/0.25 = 5\,929 \text{ sq ft}$$

Design of Duct System. The round ducts will be designed for equal-friction pressure-loss per foot of length. The final velocity at the last or most remote outlet from fan will be taken at 1 275 ft per min. The friction pressure-loss for this velocity, as read from the diagram in Fig. 76, is 0.25 in of water per 100 ft of length. There are to be eighteen outlets. The total volume of air to be discharged, measured at 145° F., is

$$1\,163/0.065 = 18\,000 \text{ cu ft per min}$$

or

$$18\,000/18 = 1\,000 \text{ cu ft per min per outlet}$$

The cross-sectional area of the outlet or last section is 1 000/1 275 sq ft, corresponding to a circular section with a diameter of 12 in. The branch-outlets may all be made the same size and provided with dampers to adjust or equalize the flow. The friction pressure-loss in the duct system is therefore

$$(212/100) \times 0.25 = 0.53 \text{ in of water}$$

The size of each section of duct is determined by locating the quantity of air at the right of the diagram and passing horizontally to the intersection with the 0.25-in pressure-loss line.

Table LXII. Data for Design of Ducts in Fig. 81

Section	Quantity of air in cubic feet per minute 145° F.	Duct-diameter in inches	Velocity in feet per minute	Measured length plus allowance for ells, in feet

J	18 000	38	2 285	..
				Total length = 212

Selection of Fan for Draw-Through Arrangement. The static pressure rating required, referred to a temperature of 70°, is.

Pressure-loss in heater (data from Table LVIII) = 0.26 in
Pressure-loss in duct (data from chart, Fig. 76) = 0.53 in
Total = 0.79 in

The actual pressure-loss will be somewhat less, owing to the fact that the air-temperature is higher (145° F.) and the density less than for air at 70° F. The actual estimated pressure-loss is therefore assumed to be $\frac{3}{4}$ in.

The volume of air the fan must handle in this example is 18 000 cu ft per min, measured at 145° F. As stated under Rating of Fans, to maintain a constant pressure the tabulated speed, volume and horse-power must be multiplied by the square root of the ratio of densities, or

$$\sqrt{0.075/0.066} = 1.07 \text{ (nearly) (Table LIX)}$$

We therefore select from Table LX a fan having a capacity, measured at 70° F., equal to

$$18\,000/1.07 = 16\,822 \text{ cu ft per min (approximately 17 000)}$$

when operating with a static pressure of $\frac{3}{4}$ in. A No. 8 Sirocco fan fulfills this requirement. The tabulated speed and horse-power when multiplied by the factor 1.07 gives

$$196 \times 1.07 = 210 \text{ r.p.m.}$$

and

$$3.76 \times 1.07 = 4.02 \text{ brake horse-power}$$

To allow for the contingency of possible overload add 20%, making the required horse-power equal to 4.82, say, a 5 horse-power motor.

Selection of Fan for Blow-Through Arrangement. In this case the fan may be called upon to handle air at a temperature of 0° F., or lower. Assuming the same weight of air, or 70 000 lb per hr, to be handled by the fan at a static pressure of $\frac{3}{4}$ in, the volume at 0° is

$$70\,000/(0.086 \times 60) = 13\,566 \text{ cu ft per min}$$

Referring to Table LXI, the ratio between the speed, volume and power necessary to produce the same pressure for air at 0° and air at 70°, is found to be 0.932. We therefore choose a fan with a capacity of

$$13\,566/0.932 = 14\,557 \text{ cu ft of air at } 70°$$

and with a static pressure of $\frac{3}{4}$ in.

Fan-Engine. When high-pressure steam is available an automatic high-speed engine is frequently employed for fan-driving, and the exhaust from the engine is used in the first section of the heater.

Selection of Motor for Fan-Driving. It is considered good practice to add from 15 to 20% to the brake horse-power, as determined from the fan-tables, for the rating of the motor, to allow for a possible overload due to the fact that the fan may not be operated under exactly the same conditions as to pressure and speed as those under which it was originally rated.

Additional Heating Requirement. It is frequently desirable to proportion the heating-apparatus large enough so that the fan may be shut down at night and started up about two hours before the shop or factory is opened in the morning. In this event it may be safely assumed that the temperature of the air in the building will not be below 30° F. when the fan is started, and that the air is all recirculated. The fan and heater must be of sufficient capacity to take care of the heat-loss from the building, including the infiltration, and in addition to warm up the contained air from 30° to 60° in two hours. Assuming the same data as given in the preceding example, the additional heat required will be, if the cubic contents of the building are 328 000 cu ft,

$$(328\,000 \times 0.08 \times 0.24 \times 30)/2 = 94\,464 \text{ Btu per hr}$$

This amounts to an increase of approximately 7% in the heating requirements as previously calculated, and is readily provided for by increasing the steam-pressure carried in the heater to approximately 10-lb gauge. Catalogues, bulletins, etc., on the subject of hot-blast heating, air-washing and humidification may be obtained from the American Blower Company, the B. F. Sturtevant Company, the Buffalo Forge Company, and the Carrier Air Conditioning Company.

Example.* **Schoolhouse Ventilating System** (see Fig. 82). It is here assumed that ventilation is to be supplied at the rate of 30 cu ft of air per minute per pupil. The heating requirements are to be taken care of by the installation of direct radiation (split system).

The air quantities and velocities assumed for the various sections of the trunk-line duct system are given by Table LXIII.

Table LXIII. Air Schedule for Typical School Layout

The pressure losses (Table LXIV), for the various sections of the duct were determined in a manner similar to the method previously given.

The bottom of all diffusers located in the walls at the end of supply risers to be 8 ft above floor-line. The vent openings to be located at the floor-line.

Unit heaters are construed to mean any combination of an indirect radiator and fan or blower, constructed or manufactured to be sold and erected as a unit having a common enclosure or casing. A motor or other auxiliary apparatus, such as valves, bypass dampers, louvers, screens, controls, etc., may or may not be included as a part of the unit, as may be specified.

* C. A. Criqui.

The heating and ventilating of buildings is frequently accomplished by means of unit heaters which incorporate in a SINGLE UNIT all the apparatus necessary for providing, directing and controlling the necessary volume of air heated to the proper temperature for the purpose. For schoolhouse purposes, the unit heater frequently provides for the ventilation requirements only, the heating being taken care of by direct radiation.

Unit heaters generally have no air ducts attached either to the outlets or to the inlets, the units being complete heating batteries in themselves.

They may be located in the various rooms or parts of a building for discharging warmed air into the room or building, and either entirely or partially recirculating the air, or else having a fresh-air connection for special ventilation purposes. These units, in the case of a schoolroom and sometimes in factories, are set on the floor, but more frequently in factories suspended from the roof-trusses so as to leave the floor-spaces unobstructed.

The schoolroom ventilating units are usually located under a window so that fresh air may be taken into the unit over the window-sill and under the bottom sash of the raised window. Otherwise special openings through the walls are required.

In the case of the factory units, the feature of noise produced by the air passing through the fans, heaters and ducts is not particularly important, but a specification for the schoolroom unit should state that the specified air quantities be delivered into the schoolroom without any objectionable noise

The engineering information given throughout this chapter is applicable to the calculations of heating and ventilating installations where unit heaters are to be used. The data as to sizes, capacities, etc , of the various makes of units must necessarily be obtained from the manufacturers.

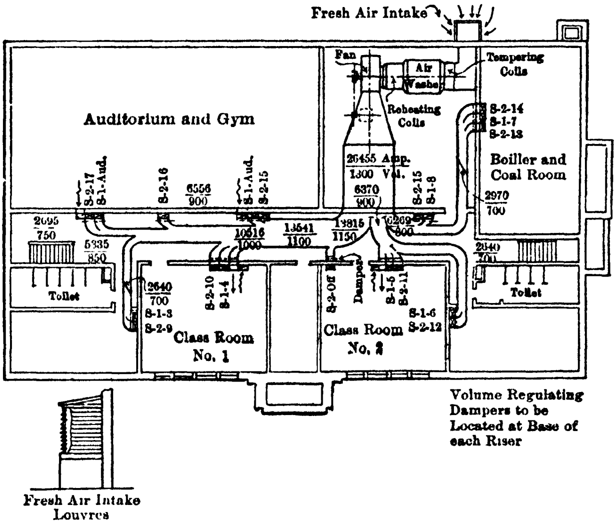

Fig 82. Metal Duct Distribution. Typical School Layout. Basement Plan.

Classification of Unit Heaters. Unit heaters may be broadly classified in accordance with the type of building they are designed to serve: (1) SCHOOLS and PUBLIC BUILDINGS, (2) INDUSTRIAL and FACTORY-BUILDINGS.

School and Public-Building Class. This class, usually located under a window, consists of a small ventilating fan or fans of the enclosed multivane type, fan motor and indirect heating surface of either copper or cast iron all enclosed in a finished sheet-steel casing provided with an outside air intake and recirculation intake. Each intake is provided with a damper and the dampers are usually so connected that the full opening of one closes the other. The fan draws in either all outside air, all recirculated room air, or a mixture of the two as may be desired.

One type of unit heater in this class is shown by Figs. 83–84.

The weight of air M to be circulated per hour is fixed by the ventilating requirements, usually 25 to 30 cu ft per minute per occupant of the room measured at 70° F.

If N = number of occupants;

then $M = N \times 30 \times 0.075 \times 60 = 135\,N$

Case I. If no direct radiation is installed, the entire heating and ventilating requirements must be taken care of by the unit heaters.

Let H = heat loss of room Btu per hour;

t = temperature to be maintained in the room;

t_y = temperature of air leaving the unit (see manufacturers' tables).

$$H = 0.24\,M\,(t_y - t)$$

$$t_y = \frac{H}{0.24\,M} + t$$

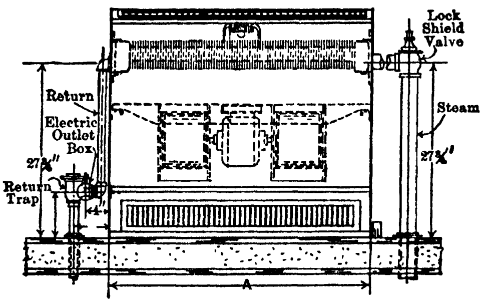

Fig. 83. Unit-heater, Type A Peer Vent

The amount of heat to be supplied by the heater will depend entirely on the amount of outside air and its temperature that must be circulated in accordance with the ventilating requirements.

Let t = temperature of outside air.

If all outside air must be employed and H_1 = heat to be supplied by the indirect heater in Btu per hour, then

$$H_1 = 0.24\,M\,(t_y - t_0) \tag{1}$$

If all of the air is recirculated,

$$H_1 = 0.24\,M\,(t_y - t) \tag{2}$$

This is the same amount as would be required from the direct radiation.

The heating surface to be installed is based on Equation (1) and as the heat loss H of the room varies, the bypass damper, under thermostatic control, automatically bypasses more or less air around the heater, thus controlling the temperature of the air t_y entering the room and consequently the heat which this air gives up to balance H.

Case II. Heat loss of the room, H, is to be taken care of by the installation of direct radiation and the ventilating requirements by unit heaters.

The area in square feet of direct cast-iron radiation to be installed = $\frac{H}{R}$, in which R = Btu emitted per square foot per hour by cast-iron radiator (usually assumed 240). In this case t_y should be equal to or slightly higher than the room temperature, t, to be maintained, usually 70°.

Then $H_1 = 0.24\,M\,(70 - t_0)$. The total heat to be supplied in this case will be $H + H_1$ Btu per hour.

We have assumed in the above formula a unit heater having the actual capacity required with $t_y = 70°$. Actually, however, it is necessary to employ a standard unit heater. These units are rated on a basis of cubic feet per minute C delivered at a certain temperature t_y with an initial temperature t_0. Choose the nearest size heater having a capacity C above 30 N cubic feet per minute, measured at 70°, the temperature t_y being stated in the table for assumed outside air temperature, t_0.

The heat available from the unit heater for heating the room, H_h, will be

$$H_h = 0.24 \times 60 \times C \times .075 \times t_y - t) \text{ Btu per hour}$$
$$(0.075 = \text{density of air at } 70°)$$

Subtract this amount from H in determining the direct radiation to be installed; or the square feet of direct radiation actually to be installed will be $\dfrac{H - H_h}{R}$.

The heat to be supplied to the ventilating unit will be

$$H_v = 0.24 \times 60 \times C \times 0.075\,(t_y - t_0) \text{ Btu per hour}$$

The total heat to be supplied both the direct and indirect radiation will therefore be

$$(H - H_h) + H_v \text{ Btu per hour.}$$

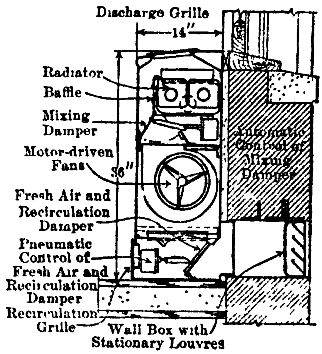

Fig 84. Section Through Peer Vent Unit-heater

Example, Case I. Assume a schoolroom designed for 40 pupils with a heat loss $H = 30\,000$ Btu per hour, both heating and ventilating requirements to be taken care of by unit heaters.

$t = 70°$. $t_0 = 0$. All fresh air to be circulated at the rate of 30 cu ft per minute per pupil

$$M = 40 \times 30 \times 0.075 \times 60 = 5\,400 \text{ lb per hour}$$

$$t_y = \frac{30\,000}{0.24 \times 5\,400} + 70 = 93.1°$$

$$H_1 = 0.24 \times 5\,400\,(93 - 0) = 115\,506 \text{ Btu per hour}$$

Assuming 2-lb gauge steam-pressure, and corresponding latent heat of 970 Btu per lb, the condensation per hour will be $\dfrac{115\,506}{970} = 119.1$ lb.

Example, Case II. Assume the same data as in the preceding example. The volume of air required for ventilation based on 30 cu ft per min per pupil is $30 \times 40 = 1\,200$ cu ft per min.

The equivalent amount of direct radiation required is $30\,000 \div 240 = 125$ sq ft.

Referring to a manufacturer's rating table, we find that the amount of direct radiation which a certain unit will replace or that can be omitted is

74 sq ft; therefore the actual direct radiation to be installed will be approximately 51 sq ft.

Factory-Type Unit Heaters. The complete unit consists of a fan or fans, indirect heating surface of pipe coil, cast-iron sections or copper sections, all enclosed in a sheet-metal jacket. Factory heaters are of various types, designed to be hung from the roof structure, placed on a wall-bracket, or set on the floor.

Generally, the air passing through the unit is all recirculated air as sufficient air for ventilating purposes, in the average industrial plant, is provided by the infiltration, unless odors, fumes, etc., given off by the process require outside air to be drawn into the building. If the HUMIDIFICATON of the air is a requirement, combination unit heaters are on the market in which there is an air washer, provided with a water heater, capable of saturating the air passing through the unit. A fresh-air intake is usually provided, in this case, so that cooling of the air for ventilation during the summer months may be accomplished.

There are a large number of factory-type unit heaters on the market but space will not permit of illustrating any unit heaters of this class.

The installation of floor-type unit heaters with recirculation in single-story industrial buildings will effect a saving in the fuel required for heating variously estimated from 10 to 30% as compared with direct radiation. The initial cost of the unit-heater installation is less than the equivalent direct-radiation installation.

The saving in fuel is effected by recirculating the air at a lower level, which produces lower air temperatures at the higher wall elevations and under the roof deck than is obtained with direct radiation, the heat loss of the building thus being reduced.

This class of heater is rated by the manufacturer on a basis of Btu output with recirculated air at 60° – 65° F., the number of units required of any certain size being determined by dividing the calculated heat-loss of the building (H) by the Btu output of the unit selected. Consult manufacturers' literature for further information in reference to unit heaters and their rating.

Ventilation

Natural and Mechanical Ventilation. Ventilation, whether NATURAL or MECHANICAL, consists in the displacement of vitiated air from an apartment and its replacement by fresh air. To state that the air in an apartment is renewed any given number of times per hour is not strictly accurate, as a positive change does not actually occur; the incoming air mixes with and dilutes the foul air to a point suitable for healthful respiration. In NATURAL-VENTILATION systems the movement of the air in flues, ducts, etc., is induced solely by the thermal head produced by the difference between the density of the column of air in the ducts and that of the outside atmosphere; the higher the temperature in the ducts the more powerful the draft. The direction and velocity of the wind materially affect the natural ventilation, retarding or accelerating the movement of the air through ducts and flues, according to the exposure of the building and the position of inlets and outlets. In MECHANICAL VENTILATION the movement of air is positively maintained by means of various types of fans, driven by an engine or electric motor. With fans of known efficiencies the results can be accurately estimated. The principal advantages of the use of mechanical systems of heating and ventilation have already been stated under Hot-Blast Heating.

Systems of Ventilation. Ventilation systems are also broadly divided into two general classes known as the UPWARD SYSTEM and the DOWNWARD SYSTEM. The UPWARD SYSTEM (Fig. 85) is sometimes used for audience-rooms where

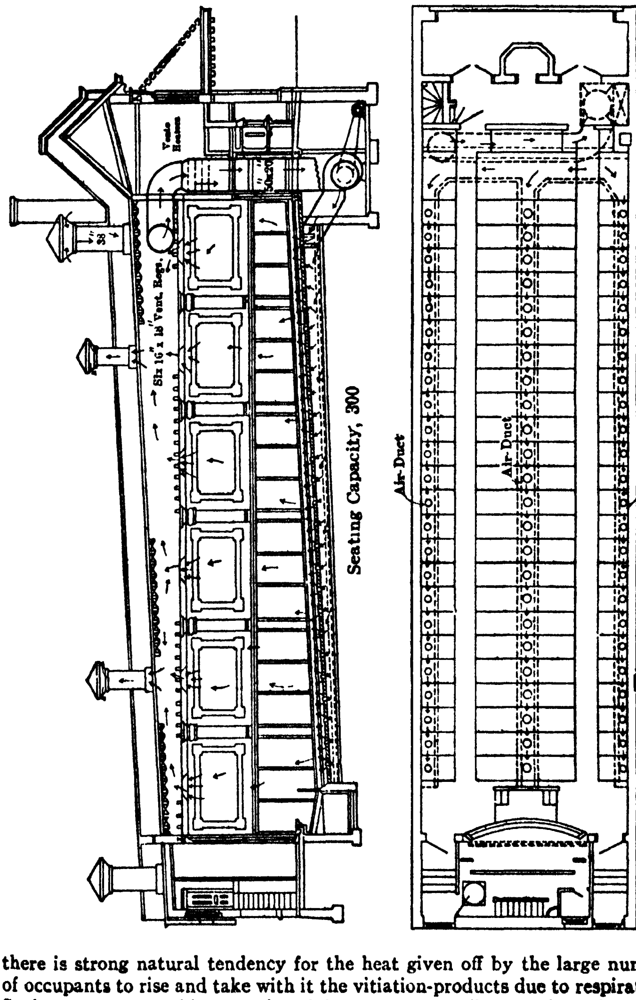

Fig. 85. Small Moving-picture Theater. Upward System Ventilating

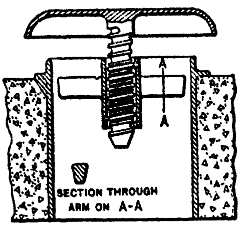
there is strong natural tendency for the heat given off by the large number of occupants to rise and take with it the vitiation-products due to respiration. Such systems are seldom employed for summer ventilation when air cooled below the average desired room temperature must be introduced. Upward systems are not always a success for winter ventilation and many designers prefer a downward system for both summer and winter conditions. The

AIR IS SUPPLIED NEAR THE FLOOR-LINE through mushroom ventilators in the floor, or through the hollow pedestals of the chairs themselves, or through low registers. The VITIATED-AIR OUTLETS ARE IN OR NEAR THE CEILING. This system makes it rather difficult to heat the room in advance of the arrival of the audience as the outlets allow the warmed air to escape almost as rapidly as it can be introduced. The DOWNWARD SYSTEM (Figs. 87–88) is very generally used in school-rooms, hospitals, institutions, and audience-rooms, as theaters, moving-picture houses, etc. The occupants are not as closely placed in a school-room as in a theater, and a more even distribution of air and more uniform heating can be secured when the AIR IS SUPPLIED EIGHT FEET OR MORE ABOVE THE FLOOR, and the VITIATED AIR REMOVED AT OR NEAR THE FLOOR-LINE. On account of the elevation of the inlets above the heads of the occupants there is little liability of drafts, and if the outlets are on the same side wall as the inlets there is very little opportunity for short-circuiting between inlet and outlet, since the incoming air must flow out across the room to the cold outside wall before it can cool and drop to the floor-level. It is, however, necessary in the downward system, to overcome the natural tendency of the heated air from the bodies of the occupants to rise



SIZES OF "ABC" MUSHROOM VENTILATOR

Size.	Approximate Inside Diameter.	Approximate Weight
4	$4\frac{1}{8}$	6 lb
5	$5\frac{1}{8}$	10 lb
6	$6\frac{5}{8}$	15 lb

Fig. 86. Section through A B C Mushroom Ventilator

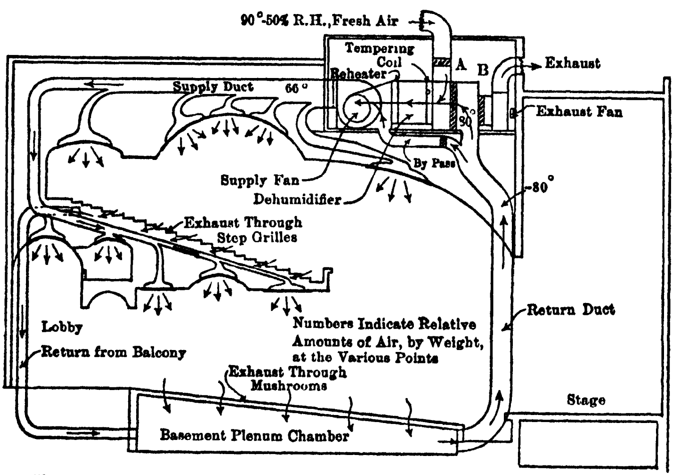


Fig. 87. Section through Theater Showing Cooling Plant. Downward System

and oppose the uniform downward tendency of the incoming fresh air. The selection of either system must depend entirely on the conditions to be met. These have been outlined in the above paragraphs.

In some recent theater and ball-room installations the EJECTOR SYSTEM (Fig. 88) has been employed. Air is introduced at a high velocity at the rear wall well above the audience through outlets unobstructed by grilles or any ceiling beams. A more vigorous circulation is possible with this arrangement than with any other method. This system is somewhat difficult to design as the size of the outlets and velocity of air must be carefully proportioned to to obtain satisfactory results.

The Effect of Vitiated Air. The amount of CARBON DIOXIDE present in vitiated air has been, until recently, quite generally understood to be the element of danger that should be kept within safe limits. Dr. Ira Remsen has pointed out that the presence of carbon dioxide in itself is not dangerous to health except that it reduces the supply of oxygen by displacing it. Carbon dioxide is not poisonous, but the ORGANIC IMPURITIES that are exhaled at the same time with other gases that are given off may prove a menace to health. The ill effects of breathing air in a poorly ventilated room are due to the small

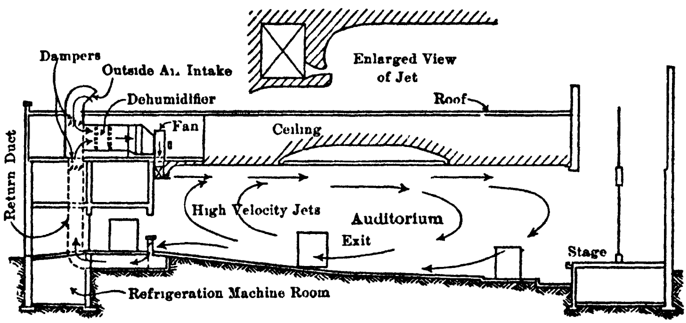

Fig. 88. Section through Theater Showing Ejector System

quantities of decomposing organic matter and unhealthful gases. The carbon dioxide generated by the lungs and given off at the same time as the other impurities serves more or less as an indicator of the presence of the real danger. Any lowering of the oxygen-supply that is actually required for the proper and necessary transformation of the potential heat-value of the food into the physical and nervous energy required to keep the human machine running, and to readily supply the additional demand made upon that machine to perform external work, means that industrial workers who perform their duties in a vitiated atmosphere do so at the expense of a lowered vitality, and are naturally less productive. Satisfactory ventilation consists not only in constantly supplying, in a pure condition, fresh air FREE FROM ODORS, DUST AND OTHER IMPURITIES, at the proper temperature and WITH THE PROPER AMOUNT OF MOISTURE PRESENT, but also in efficiently removing the vitiated air. This cannot be positively or satisfactorily accomplished during the heating-season by simply opening the doors and windows. Some mechanical means must be employed.

Relation between Humidity and Temperature. The proper and healthful RELATIVE HUMIDITY OF THE AIR in buildings has only in recent years been given the thought and attention it rightfully deserves. Heated or warmed air, whether purposely introduced into a building for warming, or naturally entering by infiltration, on being expanded by heat, has its percentage of moisture

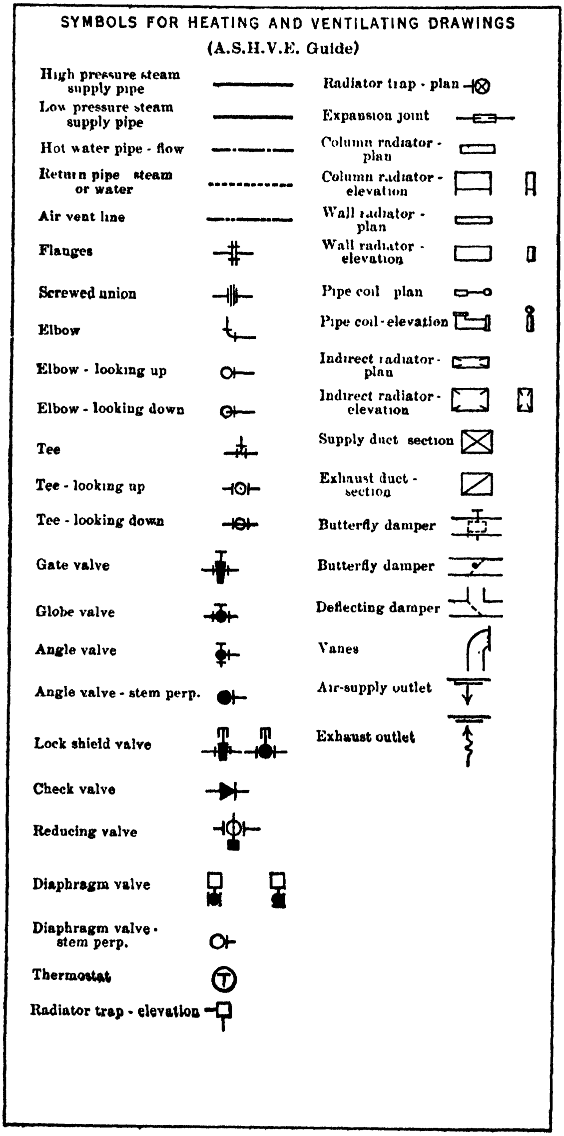

Fig. 89. Heating and Ventilating Symbols

or relative humidity lowered, and consequently its CAPACITY FOR ABSORBING MOISTURE greatly increased. There is, therefore, experienced the sensation due to so-called DRY HEAT. This causes an excessive and unnatural evaporation of moisture from the skin and from the membranes of the respiratory organs. Evaporation takes place by the direct application of heat and is essentially a refrigerating or cooling process. The abstraction of heat from the body for this purpose naturally tends to lower the surface-temperature, and one feels several degrees cooler than the temperature recorded by the thermometer in the room. Human comfort as affected by TEMPERATURE, HUMIDITY, and AIR MOTION has been a subject of research for a number of years by the research staff of the American Society of Heating and Ventilating Engineers. It has become standard practice, in this country, to install mechanical ventilating systems equipped with air-washers, heaters and refrigerating apparatus in all important moving-picture theaters and assembly-halls, the control of the temperature and relative humidity being made automatic. A STANDARD RELATIVE HUMIDITY may be obtained when mechanical ventilation is used by the addition of a HUMIDIFIER to the system.

Ventilation and Air-Conditioning Standards

Extract from A.S.H.V.E. Ventilation Code (1934)

Air Quantity. Not less than 30 cu ft per min of air to be circulated through room per occupant.

Not less than 10 cu ft per min of air to be drawn into the system from outside per occupant.

Temperature and Humidity. The maintained inside relative humidity (R.H.) shall not be less than 30% or more than 60% when heating is required. The effective temperature range shall be between 64° and 69° F, and 69° to 73° F when cooling is required. (See comfort zone—Comfort Chart).

Air Motion. The air velocity through room measured 36 in above floor line shall not exceed 50 ft per min.

Air Distribution. The air shall be distributed and circulated so that the variation in carbon dioxide concentration shall not exceed one part in 10,000 measured 36 in above floor line. The data following are not a part of this Code.

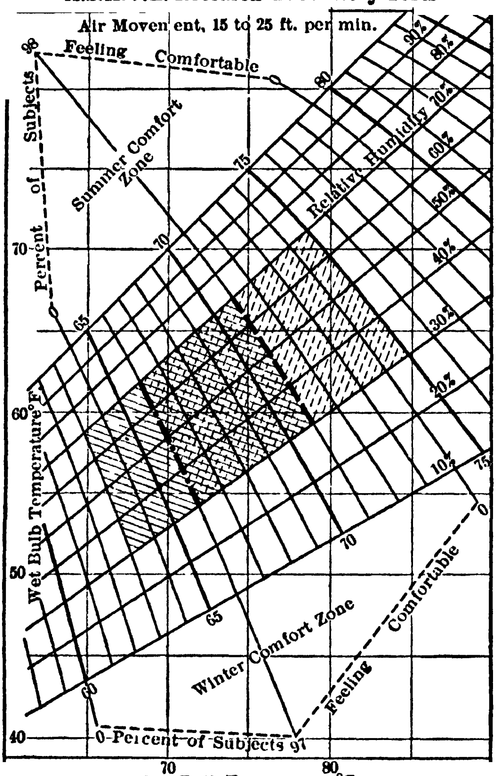
Table LXV. The Usual Requirements for Air Supplied per Person are as Follows (G. D. Small)

HOSPITALS	Ordinary	from 35 to 40 cu ft per min
	Epidemic	80 cu ft per min
		Air-change
	Detention-rooms	6 min
	Toilet-rooms	6 min
	Bath-rooms and duty-rooms	8 min
	Kitchens	3 min
	Serving-rooms	10 min
	Fumigating-rooms	10 min
WORKSHOPS	25 cu ft per min	
PRISONS	30 cu ft per min	
THEATERS	from 20 to 30 cu ft per min	
MEETING-HALLS	20 cu ft per min	
SCHOOLS	30 cu ft per min per child and 40 cu ft per min per adult	

Air-Conditioning for Comfort. The A.S.H.V.E. Research Laboratory conducted a series of experiments to determine various combinations of temperature, relative humidity, and air motion to be maintained in an occupied space, which produce a feeling of comfort for the occupants.

COMFORT CHART

A.S.H.V.E. Research Laboratory Tests



Average Winter Comfort Zone
Average Winter Comfort Line
Average Summer Comfort Zone
Average Summer Comfort Line

The results of these experiments have been embodied in a series of charts based on persons normally clothed for either the winter and summer season and for various velocities over the subjects.

Ventilation-Laws. The number of VENTILATION-LAWS has increased very rapidly in the last few years, not only as regards the number of states which have added such laws to their codes, but also as to the scope and effectiveness of these statutes. In many cases a special ventilation-officer or commission has been appointed to see to the enforcement and extension of the requirements for compulsory ventilation, so that it behooves the architect or engineer to become thoroughly familiar with the law of the state or states wherein he practices. These laws in many cases attempt to provide definite regulations for heating and ventilating all classes of public and school buildings. Future legislation will undoubtedly take a more specific form, establishing complete and definite codes for the heating and ventilation not only of public buildings but of workshops, factories and mercantile establishments as well.

Air-Conditioning. Under this heading belong the problems relating to air-washing, humidification, dehumidification, cooling and drying.

A clear understanding of the principles and laws governing air and vapor mixture, termed PSYCHROMETRY, is essential to solve satisfactorily air-conditioning problems. By air-conditioning is meant present day methods and appliances for controlling air cleansing, humidification, heating and cooling, to provide throughout the year conditions within buildings satisfactory to human comfort and health Space limitations do not permit treating this somewhat complicated subject in this chapter.

Typical Specification for a Low-Pressure, Vapor or a Vacuum System of Heating

(NOTE: Use only such description and headings in the following specification as apply to the system contemplated.)

General. This Contractor shall provide all the necessary tools, appliances, construction equipment, temporary scaffolding, supports, etc., as may be required to install the complete heating system hereinafter described.

This Contractor will be bound by the provisions of the detail general conditions, which form a part of the contract documents for the general contract for the building and which will also be made a part of the contract documents for the sub-contract for heating. (If the contract for heating is to be let direct and is not a part of the general contract, it is recommended that the Architect include with this specification such part or parts of "The General Conditions of the Contract for the Construction of Buildings" standard form of the American Institute of Architects, as he may desire to incorporate as part of the contract documents for this work. It is recommended that the standard printed form be employed with such deletions and changes as the Architect may desire).

This Contractor shall do all excavation work, cutting, drilling and patching as may be required to install the heating system and when completed shall remove all temporary scaffolding, debris, etc., resulting from his operations, from the building and property.

This Contractor shall in no case cut or drill any structural member in the building, which would tend to weaken the structure, without first securing permission in writing from the Architect.

This Contractor shall be held responsible for the safety and condition of all materials delivered to the site as required for this operation and all work done until such time as the complete system has been accepted by the Architect.

All materials furnished shall be new and in first-class condition. The work shall be done in a neat and first-class workmanship manner.

Any materials or appliances not fully conforming to the requirements of this specification that may have been incorporated in the work shall, without delay or further notice, be removed and replaced with materials that do conform to the specification.

This Contractor shall repair any and all damage, of any kind, nature or description, to the building that may result from his operations, in a manner that is satisfactory to the Architect before the work will be accepted.

Description of Work. This Contractor shall install a complete (low-pressure, vapor or vacuum) system strictly in accordance with the heating plans, details for same and the following specification:

This system has been designed and apparatus selected to maintain an average breathing line temperature within the building of 70° F. when the outside temperature is (....°) and when operating with a steam pressure of .... lb per sq in gauge at boiler.

Boiler. The boiler to be a hand-fired, low-pressure (cast-iron round or sectional type or steel type) provided with a minimum grate-area of .. sq ft, as manufactured by (list the names of manufacturers acceptable here) designed to burn (anthracite, bituminous, coke, gas or oil) as fuel. (State here character of solid fuel, if same is to be employed, Btu value of gas or oil. If solid fuel is to be employed state the "firing period" in hours desired when the boiler is carrying the load for the temperature conditions for which system is designed.)

This boiler shall be guaranteed by the manufacturer to have been constructed and tested in accordance with the A.S.M.E. Boiler Construction Code.

This boiler shall be connected to a chimney or stack .... in × .. in inside dimensions by . .. ft in height provided by others.

The boiler shall be equipped with rocking grates suitable for fuel specified for solid-fuel boiler, damper in smoke outlet and undergrate damper; 1 accurate pressure gauge ...., in diameter (brass or nickel-plated) with scale reading up to 30 lb per sq in with non-syphon connection to boiler; 1 water column with gauge glass and two trycocks; 1 pop safety-valve set to relieve at . . lb per sq in, complying with A.S.M.E Standards (for vapor systems the valve is usually set to blow at 3 lb per sq in); 1 brass draw off cock; 1 all-metal-type steam-regulator with bellows-type diaphragm for damper control; a full set of firing and cleaning tools supplied by the boiler manufacturer as standard equipment.

Boiler Foundation and Ash-Pit. This Contractor shall construct a concrete boiler foundation and ash-pit, including all excavation and back-filling required, in accordance with the detail for same as furnished by the manufacturer of the boiler.

Smoke-Flue. Connect boiler smoke-outlet to chimney or stack with a round flue the same size as boiler smoke-outlet. Provide a damper with segment-type handle in this flue. Flue to be constructed of galvanized sheet steel (or iron).... U. S. gauge. This flue and its connection with the chimney to be made tight.

Pipe and Fittings. All pipe employed must be new, free from scale or rust, full weight (mild steel or genuine wrought iron). All screwed piping must be fitted with occasional flange unions. Straighten all pipe, ream all ends to remove the burrs and remove all dirt or other material from pipe, fittings and valves before erection.

All fittings employed shall be standard-weight gray iron, recessed type, straight, true, accurately threaded, free from blow-holes and other defects. Where pipe size is reduced in a line, reducing couplings or reducing fittings are to be employed; bushings will not be permitted in these cases.

All runs to be straight and parallel with building lines and all risers to be plumb and straight.

Steam and return-mains shall be graded in the direction as indicated by the drawings and with the minimum grades, as indicated, which are 1 in in 40 ft for steam and dry return-mains and 1 in in 100 ft for wet return-mains. If it is found impossible to obtain the grade in mains as called for by the plans then a "rise and drip" shall be provided at suitable points connecting with a wet return or connected with a dry return through a thermostatic trap.

Pipe-Supports. The steam and overhead dry return-mains shall be supported at intervals not exceeding 10 ft

The hangers employed shall be expansion or adjustable (style and manufacturer's name).

Blow-Down Connection. Install a blow-down connection run to floor-drain in boiler-room, if practical. This connection to be provided with brass blow-down valve and brass cock,

Feed-Water Connection. Connect boiler with outlet in water-main, left by plumber for this purpose, with ¾-in galvanized pipe provided with one brass stop-cock and one brass globe-valve.

Boiler Connections to Steam and Return-Main. Connect all steam outlets on boiler, without reduction, to steam-main as indicated by the plan. Suitable provision has been made to provide for expansion.

(If more than one boiler is to be installed an iron body globe-valve should be specified to be installed in each boiler-lead The main return-connection to each boiler must also be provided with a valve in order to isolate the boiler from the system)

The boiler lead shall be provided with a tee the outlet of which is connected to the steam-main, the lead to be continued beyond this tee and terminated in an ell connected with the wet return to provide for relief. (See Fig. 20.)

The main return shall be connected to the boiler through a hydraulic loop. Top of loop to be 4 in below the mean water-line of boiler.

Supply and Return-Risers and Branches. The supply and return-risers are to be run as indicated by the plans Risers are to be run (exposed or concealed) and are to be of pipe sizes indicated by the plans.

All horizontal branch radiator-connections are to be graded back to risers with as much grade as is possible to obtain and not less than 1 in in 5 ft.

All connections are to be made with ample provision for expansion and IN NO CASE IS A BRANCH CONNECTION TO HAVE A POCKET.

Floor and Ceiling-Plates. Nickeled plates are to be provided wherever an exposed pipe passes through a floor, ceiling or partition. These plates are to be (style and name of manufacturer).

Direct Radiation. Direct radiation shall be installed at locations shown by the floor-plans. All radiation to be either (names of acceptable manufacturers).

(Give a list of radiation to be installed, including the floor and room, type, number of sections, height and manufacturer's rated surface for each radiator.)

Radiator Enclosures. (Give a list with location of each radiator to be provided with enclosures. State material, style, manufacturer's name and finish desired.)

Radiator Inlet Valves. All radiators shall be provided with nickel plates, rough body, graduated or modulating type inlet valve with wood handle. These valves are to be (manufacturer's name). The size of valves to correspond to the following schedules:

¾ in not exceeding 30 sq ft	1¼ in not exceeding 120 sq ft
1 in not exceeding 55 sq ft	1½ in not exceeding 190 sq ft

Orifices or Regulating Plates. (For Vapor or Vacuum System.) All radiator inlet valves to be provided with orifice plates. The diameter of the orifice in each case to be proportioned to the amount of radiation served by the radiator valve for the pressure to be carried.

Air-Valves. (For Low-Pressure Steam Systems, either one-pipe relief or two-pipe low-pressure systems) Each radiator shall be provided with a nickel-plated air- and vacuum-valve of an approved make, guaranteed to eliminate the air from the radiator, not bellow steam or water and to prevent the return of air to the radiator (type or style and name of manufacturer).

(It is very essential that only first-class air-valves be employed to obtain satisfactory heating results)

The ends of the steam-mains are to be provided with the same type of non-return air-valve as installed on the radiators.

Radiator-Traps. (For Vapor and Vacuum Systems.) The return end of each radiator shall be provided with a (style and manufacturer's name) nickel-plated, rough body, thermostatic-type trap.

The size of the trap in each case must correspond to the manufacturer's listed rating for the amount of direct radiation to which the trap is connected.

Drip-Traps. (For Vapor and Vacuum Systems.) Thermostatic-type traps are to be provided for dripping risers, etc., where called for by the plans. These traps are to be of the same make as provided for the radiators.

Dirt-Traps. (Vacuum and Vapor Systems.) The bottom of all steam-risers that are dripped into a dry return-main through a thermostatic-trap must be provided with a dirt-pocket. The drip from steam-mains, connecting with a dry return through a thermostatic-trap must also be provided with at dirt-pocket.

Lift-Fittings and Strainer. (Vacuum System.) The suction line to the vacuum-pump to be provided with lift-fittings and a strainer (if required), as indicated by the drawings.

Vacuum-Pump and Receiver. (Vacuum System.) This contractor shall furnish and install one (rated size or number and manufacturer's name) motor-driven vacuum-pump. The current supplied is (....volts direct or ....phase ....cycle ....volts alternating current).

The motor shall be of ample capacity to operate continuously without undue heating or overload. Pump to be bronze fitted throughout, including the water-impeller and air-rotor.

The control shall be dual automatic so arranged that the pump will be started or stopped by either the water-level in the receiver or by the vacuum carried on the system.

The pump shall be provided with a strainer, vacuum gauge, vacuum regulator and relief-valve. The size installed must conform to the manufacturer's listed rating for the amount of installed radiation. The Contractor shall provide the Owner with a copy of the manufacturer's guarantee for this pump. The piping connections to pump must be installed strictly in accordance

with the manufacturer's recommendations. This Contractor shall install the necessary wiring run in metal conduit between the motor and starting-switch.

(In case some radiation is located below the strainer connection of pump, it becomes necessary to install an auxiliary tank, provided with float switch on the return line near pump.)

Insulation and Pipe-Covering. Before any insulation or pipe-covering is installed, the system shall be tested as specified under Tests.

All steam and dry return-mains and steam-risers shall be covered with (specify thickness and type of covering desired, usually 1-in thickness or 4-ply asbestos air-cell sectional covering with canvas jacket secured to the pipe with lacquered metal bands).

Cover all fittings and valves, except radiator valves and return traps, with asbestos cement, approximately 1 in in thickness, troweled smooth and finished with a canvas jacket smoothly pasted on the asbestos. The canvas to have the same weight as that used on the pipe-covering.

The boiler shall be covered first with 1 in thickness of magnesia blocks or (.. ..) insulating blocks securely wired in place with 2-in hexagonal wire mesh stretched tight and finished smooth and neat with ½ in thickness hard-finish plastic asbestos cement, the total thickness of insulation to be approximately 1½ in. Cover insulation with a canvas jacket smoothly pasted on same.

(If the boiler is provided with an insulated metal jacket by the manufacturer obviously no further insulation will be required)

Pipe-Sleeves. This Contractor shall furnish and set a pipe-sleeve in the floor or partition construction for every pipe passing through same.

Painting. The exposed surface of all radiators shall receive two coats of special radiator enamel paint applied by this Contractor (or painting contractor). The paint and color for same to be selected by the Architect. All paint shall be delivered to the job in the original package and to be applied strictly in accordance with the paint manufacturer's specification. Before the paint is applied, the exposed surface of all radiators shall be thoroughly cleaned of dirt and rust scale by means of a wire brush.

The finished paint must be smooth, neat and clean before it will be accepted by the Architect.

(If the pipe covering is to be painted include specification for same under this heading)

Automatic Temperature Control. (If automatic temperature control is contemplated, a complete description of the system and apparatus desired should be included under this heading.)

Cleaning Boilers. The safety-valve is to be removed and a temporary line connected to this opening, or highest opening on the boiler, and discharging into sewer. Place a sufficient quantity of soda ash inside the boiler to cause saponification of the oil and grease when mixed with boiling-hot water. A moderate fire to be kept in the boiler sufficient to cause foaming and removal of the grease and oil through the temporary waste-connection as fresh water is gradually fed to the boiler through the boiler feed-line.

After the above-mentioned treatment, the boiler shall be thoroughly washed out with fresh water to remove the dirt, scale, and chemicals, the wash water to leave boiler through the blow-off line or from the lowest opening in the boiler. If foaming should occur later with boiler in operation the above treatment must be repeated by this Contractor until the cause has been removed.

Blowing-Out System. All piping and radiation shall be thoroughly blown out with live steam after having first removed the thermostatic element from the return radiator and drip-traps and the system operated several days with the condensation being wasted to the sewer. This work shall be done before any tests are applied to the system.

Temporary Setting of Direct Radiators. Each bidder shall state in his proposal his charge for connecting each radiator required for temporary heat, including the disconnecting of the radiator, and cleaning of it. Temporary radiators shall be supported from the floor on wood blocks and placed at a sufficient distance from the wall so that the wall finish, millwork, etc., may be applied without interference by the radiator.

The Architect's representative in charge of the work will designate what radiators are to be temporarily connected by this Contractor.

Fuel and Attendance for Temporary Heat. The cost of fuel and attendance required for temporary heat shall be paid for by the (Owner or Contractor). If Owner is to pay for this service the cost is to be determined on a basis of the cost to the Contractor for fuel, water, supplies, and electric power, plus the labor cost including labor insurance plus ...... per cent for overhead supervision and profit.

The Contractor shall submit original invoices showing cost of the fuel delivered on site, supplies, water cost, electric power cost, cost of removal of ashes and original payroll sheets, which must be approved by the Architect's representative in charge of the work. No costs are to be included by the Contractor except those enumerated.

(If Contractor is to include the cost of temporary heat in the contract price, then the specifications should clearly state what is to be required, and the length of time temporary heat is to be supplied. In either case the Contractor is to assume full responsibility for the operation and condition of the heating system, at all times, until final acceptance of the completed contract.)

Request for Samples.—The following samples of materials are hereby requested to be submitted by successful bidder before the contract will be awarded (list to follow):

Tests. (Economy tests for heating boilers and other heating equipment are not usual. If any tests of this character are required the conditions under which the tests are to be conducted must be clearly outlined, covering all points involved. (See A.S.H.V.E. Heating Boiler Test Code.) The following tests are, however, usual)

All concealed low-pressure piping shall be tested and remain tight under a hydraulic pressure of 50 lb per sq in before being covered in. The entire system shall be tested under ...... (usually 10) lb steam-pressure. All such tests to be made in the presence of the Owner's representative.

Material and Workmanship Guarantee. The work herein specified shall be done by competent workmen in a satisfactory manner acceptable to the Architect's representative in charge of the work.

The Contractor shall, upon notice given by the Architect's representative, replace any man or men in the employ of the Contractor on this work, who, in his opinion, are detrimental to the best interests of either the Owner or Contractor in completing the work herein specified in a manner which strictly complies with the specifications and time limit set for completion.

The entire system when completed shall be tested in the presence of the Architect's representative as outlined under Tests.

The Contractor shall make good at his own expense any defects in mate-

rials, furnished under this specification, or workmanship which may develop for a period of one year from the date of completion of the entire contract.

Any leaky joints found shall be made good without calking Split or defective pipe shall be removed and replaced by good pipe. Defective castings shall be removed and replaced by good castings. Any part of any piece of apparatus which is found to be defective shall be replaced in the system by the Contractor free of expense to the Owner.

The Contractor, if requested, is to furnish the Owner with a duplicate of the manufacturer's guarantee of any piece of apparatus which the Contractor may install under this contract.

CHAPTER XXXI

CHIMNEYS *

By

LOUIS A. HARDING

FORMER PRESIDENT OF THE AMERICAN SOCIETY OF HEATING AND VENTILATING ENGINEERS

Draft. To burn a fuel at a given rate (pounds per square foot of grate-surface per hour) requires a definite weight of air to be supplied for combustion The air passes under the grate and through the fuel-bed and meets with considerable resistance in its flow, not only through the fuel-bed, but through or around the boiler-tubes and smoke-flue or breeching. The motive force causing the air-flow in a natural-draft plant is supplied by the chimney. The difference between the atmospheric pressure and the pressure existing at any point in the furnace or in the flue is termed the DRAFT at that particular point. This pressure is ordinarily measured by means of a U tube filled with water, the draft being recorded in inches of water, and is the difference in the heights of the water-columns in the two legs of the U tube.

Height. The INTENSITY OF DRAFT that a chimney is capable of producing at the base is a function of its height, the temperature of the flue-gases, and the temperature of the outside air, which is generally assumed to be 60°. The temperature of the flue-gas is ordinarily assumed to be 550°. The intensity of draft produced, per foot height, measured in inches of water is

$$H = 0.0071\,L$$

L = height of chimney above grate, in feet. The flue-gas temperature is taken at 550° and the outside temperature at 60°. Ordinarily 0 8 H is taken as representing the AVAILABLE DRAFT, in order to allow for the cooling of the chimney gases. Then 0.8 H must be equal to or greater than the sum of the expected draft-losses as given in the following paragraphs.

Draft-Losses. The DRAFT-LOSSES through the fuel-bed depend upon the rate of combustion required and the kind of fuel. This loss may be approximated by using the data in Table I.

The LOSS OF DRAFT between the grate or furnace and a point just beyond the damper-box of a boiler is about as shown in Table II when the boilers are operated at normal rating; bituminous coal burned at the rate of from 25 to 30 lb per sq ft of grate-surface per hour.

The loss of draft through the boiler will depend largely upon the method of baffling employed, and increases with the per-cent rating at which the boiler is operated. The precipitating-figures should be increased by approximately 55% when the boiler is operated at 150% of its rated capacity, and by 75% when it is run at 200% rating.

Velocity of Gases through Flue and Chimney. In preliminary estimates 5 lb coal per boiler horse-power developed, and 24 lb air per lb of coal is usually

* See, also, Flue Sizes under Heating and Ventilation of Buildings.

assumed. The customary allowable VELOCITIES OF GASES in chimneys, when the design is based on 120 lb of the flue-gas per hour per rated boiler horsepower, varies from 17 ft per sec for a diameter of stack equal to 24 in, to 31 ft per sec for a 72-in or larger diameter. These figures correspond to a weight of 0.68 and 1.10 lb per sq ft of area. The formula that is supposed to give the most economical diameter for an unlined steel chimney or stack, and used by many engineers in this country, is $d = 4.68\sqrt[5]{(\text{h p})^2}$, in which d is the inside diameter in inches and h.p. is the rated capacity of the boilers served.

The following figures are frequently used by engineers for approximating the loss of draft in flues or breechings:

Table I. Loss of Draft between Furnace and Ash-Pit to Burn Coal

Table II. Loss of Draft between Grate or Furnace and a Point Just Beyond Damper-Box

Horizontal return tubular. .	25 to 30 in of water
Babcock & Wilcox . .	.20 to .35 in of water
Stirling . . .	51 in of water
Vertical tubular .	.43 in of water

(1) Horizontal flues, square or rectangular, from 0.13 to 0.15 in of water per 100 ft. Increase these values 50% for brick-lined flues. Loss of draft for easy right-angle bends, 0.05 in of water.

(2) When economizers are to be installed the temperature of the flue-gas is reduced to from 250° to 325°, and the total head, H, should be calculated on a basis of these temperatures.

(3) The loss of draft through the economizers should not be figured less than 0.3 in of water.

(4) The turns which the flue makes in leaving the damper-box of the boiler, where it enters the main flue and at the stack, should be considered and allowed for.

(5) It is customary to make the flue or breeching approximately from 10 to 15% greater in area than the stack to which it connects. The cross-section is reduced in proportion to the volume of gas to be handled as the flue passes the boilers in succession. The width of the flue or breeching, where it enters the

chimney, should never exceed one third the outside diameter of the chimney at its base.

Example. The method of procedure in determining the dimensions of a chimney and breeching is explained in the following example.

Three 150-h.p. return tubular boilers with a total of 1 500 sq ft of heating-surface are to be served. The total area of the grate-surface is 90 sq ft. The measured length of the breeching is 40 ft. The gas makes two right-angle turns, one at the entrance to the breeching, and one on entering the chimney. The fuel assumed is Pennsylvania bituminous coal. If 5 lb of coal per boiler horse-power per hour is assumed as the fuel-consumption, the rate of combustion is $(3 \times 150 \times 5)/90 = 25$ lb per sq ft of grate-surface per hour.

The weight of flue-gas per second is

$$(3 \times 120 \times 150)/(60 \times 60) = 15 \text{ lb}$$

Assuming a temperature of 550°, the volume of the flue-gas per second is $15/0.0393 = 382$ cu ft. Assuming an allowable velocity through the chimney-area of 25 ft per sec, the required area is,

$$382/25 = 15.3 \text{ sq ft}$$

corresponding to 54-in diam, approximately. The area of the flue is to be 15% greater, or

$$15.3 \times 1.15 = 17.6 \text{ sq ft}$$

at the last boiler next to the chimney. The chimney must produce sufficient draft to overcome the following resistance. The loss of draft through fuel-bed based on a rate of combustion of 25 lb per sq ft per hr (Table I) is 0.31 in. The loss of draft through return tubular boilers (Table II) is 0.27 in. The loss of draft through the breeching is

$$0.15 \times 40/100 = 0.06 \text{ in}$$

The loss of draft occasioned by two turns is

$$2 \times 0.05 = 0.10 \text{ in}$$

The total loss is

$$0.31 + 0.27 + 0.06 + 0.10 = 0.74 \text{ in}$$

Then

$$H = 0.74/0.8 = 0.92 \text{ in}$$

or approximately 1 in.

Substituting this value of H in the equation

$$H = 0.0071\,L$$

the height, L, of the stack is

$$1/0.0071 = 140 \text{ ft}$$

measured above the grate.

Kent's Chimney-Formulas. The following chimney-formulas by William Kent are largely used by engineers in this country: The formula is based on the assumption that the friction-head in the chimney is considered equivalent to a diminution of the area by an amount equal to a lining of inert gas, 2 in in thickness.

If A = the actual area in square feet;
E = the effective area in square feet;
D = the diameter in feet;

Then $E = A - 0.60\sqrt{A}$.

The draft-power of a chimney varies directly as the effective area, E, and as the square root of the height, L. The formula for the horse-power of a chim-

* Based on a consumption of 5 lb of fuel per boiler horse-power. For any other rate, multiply the tabular figure by the ratio of 5 to the maximum expected coal-consumption per horse-power per hour.

ney will take the form, h.p. $= CE\sqrt{L}$, in which C is a constant. The value of C as obtained by Kent from an examination of a large number of chimneys is 3.33 when 5 lb of coal is burned per boiler horse-power per hour.

The formula for the horse-power rating of a chimney is, therefore,

$$\text{h.p.} = 3.33\,E\sqrt{L} = 3.33\,(A - 0.6\sqrt{A})\sqrt{L}$$

or

$$E = 0.3\ \text{h.p.}/\sqrt{L}$$

The Babcock & Wilcox Company recommend that when the fuel used is low-grade bituminous coal of the Middle or Western States, the sizes given in Table III be increased from 25 to 60%, depending upon the nature of the coal and the capacity desired. If the gas makes more than two turns it is advisable to increase the diameter given in the table by one size. The height must be increased at least 30% if economizers are used. Table III may be applied to heating-boilers, the equivalent rating in square feet of direct radiation being approximately equal to the horse-power rating × 100.

Chimneys for Tall Office and Loft-Buildings. The chimney or stack for a tall building is a special case in which the height is frequently fixed by the height of the structure itself or the height of the adjoining buildings. In this case a diameter is assumed and the method outlined in the preceding example applied.

General Formulas for the Design of Brick Chimneys. See Fig. 1

Let P = horizontal wind-pressure in pounds per square foot, ordinarily assumed as 25 lb per sq ft for round chimneys

xx = any section distant z from top of chimney

$z\left(\frac{d + d_1}{2}\right)$ = projected area above xx

R = horizontal wind-load in pounds

$= Pz\left(\frac{d + d_1}{2}\right)$

y = distance from xx to center of gravity of portion above xx

M = wind-moment in foot-pounds

$= Pzy\left(\frac{d + d_1}{2}\right)$

PROPERTIES OF SECTION

d_1 = outside diameter

d_2 = inside diameter

$c = d_1/2$

I = moment of inertia of section

A = area of section in square feet

$= 0.7854\,(d_1^2 - d_2^2)$

$\frac{I}{c}$ = section-modulus

$$\frac{I}{c} = \frac{0.0982\,(d_1^4 - d_2^4)}{d_1}$$

W = weight of chimney above xx, in tons

S_1 = compressive stress at edge on leeward side due to W, in tons per square foot

S_2 = compressive stress at edge on leeward side due to M, in tons per square foot

$$S_1 = +\frac{W}{A} \qquad S_2 = \pm\frac{Mc}{I}$$

$$\text{Windward side, } S_w = \frac{W}{A} - \left[\frac{Mc}{I}\text{ (tension)}\right]$$

$$\text{Leeward side, } S_l = \frac{W}{A} + \left[\frac{Mc}{I}\text{ (compression)}\right]$$

S_w and S_l should not exceed the following values, in tons per square foot, for Radial Brick Chimneys:

Maximum tension		Maximum compression	
Below 150 ft. . .	2 to 2½	200 ft and below.	19
From 150 to 200 ft.	1 to 1½	Above 200 ft	21
Above 200 ft.	0		

Foundations. Calculate wind-moment, M_1 for chimney above ground-line.

$$M_1 = Phy_1\left(\frac{d + d_3}{2}\right)$$

l = length of side of square base in feet

$A_1 = l^2$ = area of base in square feet

$\frac{I}{c} = \frac{l^3}{6}$ = section modulus of base

W_1 = combined weight of chimney and foundation

Example. It is required to determine the maximum compression, in tons per sq ft at the base of the column, for the chimney shown in Fig. 2, and also the maximum soil-pressure in tons per sq ft. The assumed wind-pressure is 25 lb per sq ft. (See General Formulas for the Design of Brick Chimneys, and Fig. 1.)

The area of section at base, $A = 0.7854\,(16^2 - 12.3^2) = 80.9$ sq ft.

The section-modulus at base, $I/c = [0.0982(16^4 - 12.3^4)]/16 = 257$.

The total weight of brick column (Table V) is W = 495 tons (interpolated).

The projected area of column is $\frac{1}{2} \times (8.75 + 16) \times 180 = 2\,228$ sq ft.

The horizontal wind-load, $R = 2\,228 \times 25 = 55\,700$ lb = 27.8 tons.

The moment-arm of R is $y = \frac{1}{3} \times 180[(2 \times 8.75) + 16]/(8.75 + 16) = 81$ ft.

The wind-moment, $M = 81 \times 27.8 = 2\,252$ ft tons.

$S_1 = 495/80.9 = 6.2$ tons per sq ft.

$S_2 = \pm\, 2\,252/257 = 8.7$ tons per sq ft.

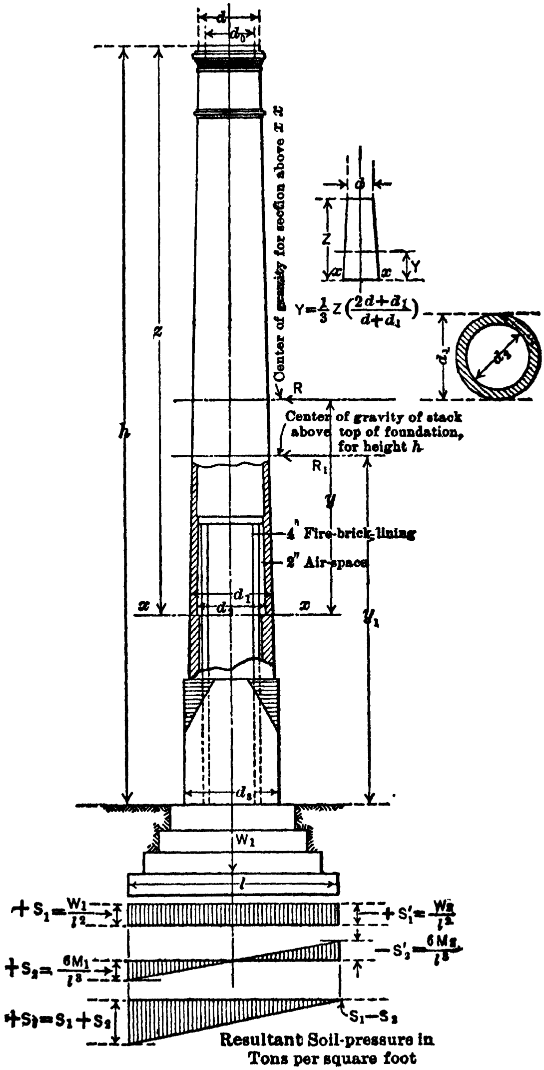
The maximum compression on the leeward side, $S_1 + S_2 = 6.2 + 8.7 = 14.9$ tons per sq ft. The maximum tension on the windward side, $S_1 - S_2 = -\,2.2$ tons per sq ft. The following computations are for a square base:

Foundation. The length of base, $l = 25.5$ ft, $A_1 = l^2 = 650$ sq ft, $I/c = 25.5^3/6 = 814$. The weight of foundation, based on 1.9 tons per cu yd, is 266 tons. The weight of the 4½-in lining is $36 \times 11 \times 0.063 = 25$ tons. The total weight of column, lining and foundation, is $W_1 = 495 + 25 + 266 = 786$ tons.

The moment-arm for R may be assumed the same as before, or 81 ft. Then $M = 2\,252$ ft-tons. The section-modulus of the base, $I/c = l^3/6 = 814$.

$S_1 = 786/650 = 1.2$ tons per sq ft. $S_2 = 2\,252/814 = 2.8$ tons per sq ft.

The maximum soil-pressure, $S_1 + S_2 = 1.2 + 2.8 = 4$ tons per sq ft.



$$S_1 = \frac{W_1}{l^2} = \text{compression per sq ft due to } W_1$$

$$S_2 = \frac{6\,M_1}{l^3} = \text{compression per sq ft due to } M_1$$

* These values are interpolated from curves by the M. W. Kellogg Company. The maximum unit soil-pressure at the outer edge of the foundation, due to dead and wind-loads, does not exceed 2 tons per square foot.

Reinforced-Concrete Chimneys. Area of Steel Reinforcement Required. The following formulas are used by one concern in the design of reinforced-concrete chimneys:

M = wind-moment at section considered, in inch-pounds;
W = weight of shell above section considered, in pounds;
D = outside diameter of shell, in feet:

d = inside diameter of shell, in feet;
R = radius of steel circle, in inches;
r = radius of neutral core = $\frac{1}{8}[D1 + (d/D)_2]$ feet;
WR = moment of stability from weight of shell, in inch-pounds;
S = 16 000, the allowable fiber-stress in the steel in pounds per square inch;
A = total cross-sectional area of steel rods required at section considered, in square inches;
$A = 2(M - Wr)/SR$ = number of bars × cross-sectional area of one bar.

The bars used are ordinarily ¾-in square, twisted bars, each with a cross-sectional area of 0 5625 sq in. The thickness of the shelf, if made without a taper, is ordinarily 6 in, and if constructed with a taper the shell is made 5 in in thickness at the top and increased ¼ in in thickness for each 5 ft in height. The maximum compression due to the wind-moment and dead load in the concrete, at the base, is ordinarily limited to 350 lb per sq in. The same formulas apply in this case as in the design of brick chimneys (Fig. 1).

Example. A reinforced-concrete chimney has the following dimensions: 150 ft high; no taper; 9 ft inside diameter; thickness of shell 6 in; outside diameter 10 ft; weight of shell 335 250 lb. It is required to determine the total cross-sectional area of reinforcement.

$M = 25 \times 10 \times 150 \times 150/2 = 2\,812\,500$ ft-lb $= 33\,750\,000$ in-lb;
$r = 10/8 \times [1 + (9/10)^2] = 2.3$ ft $= 27.6$ in;
$R = 58$ in;
$A = 2[33\,750\,000 - (335\,250 \times 27.6)]/16\,000 \times 58) = 53$ sq in;

If ¾-in square bars are used, it requires 53/0.5625 = 94 bars.

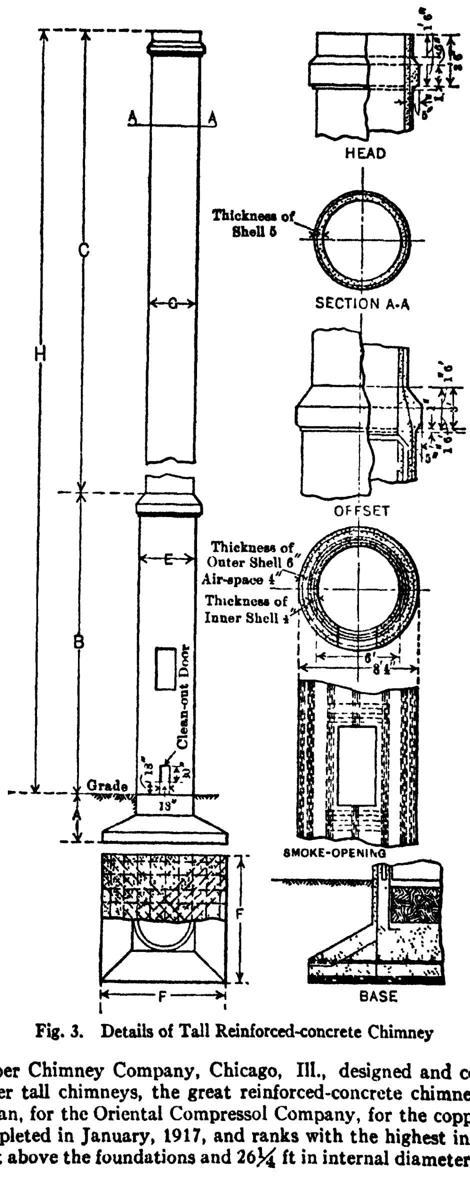

Fig. 3. Details of Tall Reinforced-concrete Chimney

The Weber Chimney Company, Chicago, Ill., designed and constructed, among other tall chimneys, the great reinforced-concrete chimney at Saganoseki, Japan, for the Oriental Compressol Company, for the copper smelter. It was completed in January, 1917, and ranks with the highest in the world, being 570 ft above the foundations and 26¼ ft in internal diameter at the top.

Self-Sustaining Steel Chimneys* are largely used, especially for tall chimneys of iron-works and power-houses from 150 to 300 ft in height.

"The advantages claimed are: Greater strength and safety; smaller space required; smaller cost by 30 to 50% as compared with brick chimneys; avoidance of infiltration of air and consequent checking of the draught, common in brick chimneys. They are usually made cylindrical in shape, with a wide curved flare for 10 to 25 ft at the bottom. A heavy cast-iron base-plate is provided, to which the chimney is riveted, and the plate is secured to a massive foundation by holding-down bolts. No guys are used."†

A large SELF-SUSTAINING STEEL CHIMNEY is that built by the Chicago Bridge and Iron Works at the plant of the United Verde Copper Company, Clarkdale, Arizona. It is 30 ft 9½ in in diameter and 400 ft in height. The thickness of plates varies from ¼ in at the top to 11/16 in for the bell-shaped portion at the bottom. The weight of steel is 800 000 lb. The stack is anchored to the foundation by thirty-six bolts, each 4 in in diameter, upset, and spaced equidistant in a bolt-circle of 25 ft 4½ in radius.

The governing feature in the design of a SELF-SUSTAINING STEEL CHIMNEY OR STACK is the force of the wind. The cylinder above any horizontal plane section may be assumed to act as a cantilever beam in which the bending moment, in foot-pounds, is

$$M = HD \times P \times \tfrac{1}{2}H = \tfrac{1}{2}H^2DP$$

in which H is the height in feet above the section considered, D the diameter in feet and P the assumed pressure of the wind in pounds per square ft on a vertical cross-section. The fiber-stress S, in pounds per square inch, according to the formula for flexure, is $S = Mc/I$. For hollow cylinders of large diameter and small thickness, the moment of inertia $I = \pi R^3 t$, in which R = mean radius in feet (equivalent to c in the flexure formula) and t = thickness of shell in inches. Hence

$$S = MR/12\pi R^3 t = 0.106\ M/D^2t, \text{ and } t = 0.106\ M/SD^2.$$

The stress S is tensile on the windward side and compressive on the leeward side. There is also a small compressive stress due to the weight of the stack. The value of P may be taken at 25 lb per sq ft and of S at 16 000 or 18 000 lb per

* Compiled from data furnished by Robins Fleming.

† Mechanical Engineers' Pocket Book. Kent.

‡ These dimensions were taken from a pamphlet published by the Philadelphia Engineering Works.

sq in. As stacks are built for durability as well as strength it is often advisable to increase the theoretical thickness of the shell. No plate should be used with a thickness less than ¼ in. It is important that the stack be securely anchored to the foundation. Many methods have been proposed for determining stresses in anchor-bolts. As the problem depends for its solution on the physical conditions of stack, base and bolts, no exact analysis is possible. The most severe assumption is that the bolts are screwed up with a high initial tension. The anchor-bolt ring can then be considered in the same way as a ring of the cylinder. The maximum stress at any point of the bolt-circle is developed when the wind is blowing parallel to the radius through that point. The stress for each circumferential inch is $0.106\,M/(2\,R_1)^2$, $2R_1$ being the diameter of the bolt-circle. Let b be the circumferential distance in inches between adjacent anchor-bolts, N the number of bolts equidistant on the bolt-circle and W the weight of the stack. For the anchor-bolt on the windward side there is a tensile stress, S_w, due to the wind,

$$S_w = 0.106\,bM/(2R_1)^2$$

Since

$$b = (2R_1 \times 12 \times \pi)/N$$

$$S_w = 2\,M/R_1N$$

Deducting the weight of the portion of the stack between adjacent bolts, the maximum tensile stress in any anchor-bolt may be expressed by the equation

$$S_w = (2\,M/R_1N) - W/N$$

Radial-Brick Chimneys. These chimneys are built with special blocks formed to suit the circular and radial lines of each section of the chimney so that the finished brickwork has joints of an even thickness throughout and a perfectly smooth surface. The blocks being much larger than common bricks, there are only from one third to one half as many joints. Radial-brick chimneys are always circular in plan above the base. The best form of base is octagonal in cross-section so as to permit the breeching to enter the chimney at a flat surface and at the same time comply best with the rules of stability. Except for chemical-works, refineries, furnaces, etc., radial-brick chimneys are built with a single shell, a lining only being provided in the immediate vicinity of the flue-entrance. All radial bricks are perforated vertically and this insures thorough burning and allows the mortar to enter the perforations, thus forming a vertical anchorage.

Radial blocks for chimney-construction have been used extensively in England, Germany, France and Russia since 1870. They were not introduced into this country, however, until 1898. In 1869 or 1870 Alphons Custodis, of Dusseldorf, Germany, originated a method of building tall chimneys of perforated radial blocks, made from selected clays and burned at a very high temperature, and in 1898 an American company * was formed for the purpose of erecting chimneys by this method of construction. Since that time the company through various agencies has built more than six thousand chimneys in all parts of the world. A very tall chimney, 585 feet high and 60 ft in internal diameter at the top, was built by this company in 1918 for the Anaconda Copper Company, at Anaconda, Mont.

Mr. H. R. Heinicke,† of Chemnitz, Germany, builder of the 460-ft stack at Halsbrücke, Germany, has employed radial bricks made especially for each

* Alphons Custodis Chimney Construction Company, New York City.

† H. R. Heinicke, Incorporated, New York City.

chimney. This firm through long and costly research has done much to make chimney-building a science. The chimney at Halsbrücke is a very remarkable one on account of its proportions. In a height of 460 ft, the diameter at the top is only 8 ft, whereas the 585-ft stack at Anaconda, Mont., has a diameter of 60 ft at the top.

The Heine Chimney Company * has erected many important high chimneys. The essential difference in the methods of construction used by this company from those of the other chimney-constructors is that the Heine Chimney Company uses perforated, INTERLOCKING, radial bricks. It is claimed that this interlocking-feature has an advantage over the straight-sided bricks in acting as a preventive of deep weathering of the joints and of air-leaks. In addition to this it is claimed that the circumferential strength of the walls when built of this type of brick is considerably greater than when built with plain-sided or corrugated bricks. The perforations in these bricks are fewer but larger than those of some of the other constructors. The brick-work is laid on full-mortar beds with SHOVED joints. These large perforations allow the mortar to rise in them, thus forming PINS which give the walls great strength and enable them to withstand the stresses due to expansion caused by the high temperature of the flue-gases. In walls more than one brick thick, the bricks are laid up in English bond, that is, with alternate header and stretcher-courses. This company advocates this method of construction even in chimneys built with the ordinary straight-sided common building-bricks. Among the many important chimneys constructed by the Heine Chimney Company is the one erected at the St. Joseph Lead Company's plant, at Herculaneum, Mo. The height of this chimney is 350 ft and the inside diameter at the top 20 ft.

The M. W. Kellogg Company † has designed and built many radial-brick chimneys for power-plants, chemical-works and other purposes. Several of the important chimneys put up by them are mentioned in the list of tall chimneys at the end of this chapter. Some of the details of construction differ from those of the other companies mentioned. One of the points of difference is the detail relating to the corrugations on their bricks. These corrugations are 3/8 in wide and 1/8 in deep and are placed along the vertical sides of the bricks as they lie in the wall. The adhesion between the bricks and mortar is increased by this increased area. It is claimed that tests made show that this is the case. On account of these corrugations it is not considered necessary to embed any ironwork in these chimneys to prevent the development of cracks due to heat-expansion. Ironwork has sometimes been inserted when plain-sided bricks have been used. It is claimed that this design is somewhat heavier than that employed by some other constructors, this company holding that it is not safe to figure on wind-pressure of less than 25 lb per sq ft of projected area. Among the many tall chimneys erected by this company may be mentioned especially the chimney at Douglas, Ariz., erected for the Copper Queen Consolidated Mining Company.

There are other reliable companies which design and construct tall chimneys. Those mentioned here were the pioneers in this work.

CHAPTER XXXII

HYDRAULICS, PLUMBING AND DRAINAGE, ILLUMINATING-GAS AND GAS-PIPING

By
J. J. COSGROVE
CONSULTING ENGINEER

1. Hydraulics

Water is practically an imcompressible liquid, weighing, at the average temperature of 62° F., 62.355 lb to the cu ft and 8.335 lb to the gallon. These figures change slightly with changes in temperature and atmospheric pressure, and a slight variation for the same temperature will be found in different works. 62.4 lb per cu ft is the weight of water used for ordinary computations.

Pressure of Water. The pressure of still water in pounds per square inch against the sides of any pipe or vessel of any shape whatever is due alone to the HEAD, or height of the surface of the water above the point considered pressed upon, and is equal to 0 433 lb per sq in for every foot of head at 62° F. The fluid-pressure per square inch is equal in all directions. To find the total pressure of quiet water against and perpendicular to any surface, whether vertical, horizontal, or inclined at any angle, whether it be flat or curved, multiply together the area in square feet of the surface pressed, the vertical depth of its center of gravity below the surface of the water, and the constant 62.4. The product will be the required pressure in pounds. This may be expressed by formula as follows:

$$P = 62.4\,AD$$

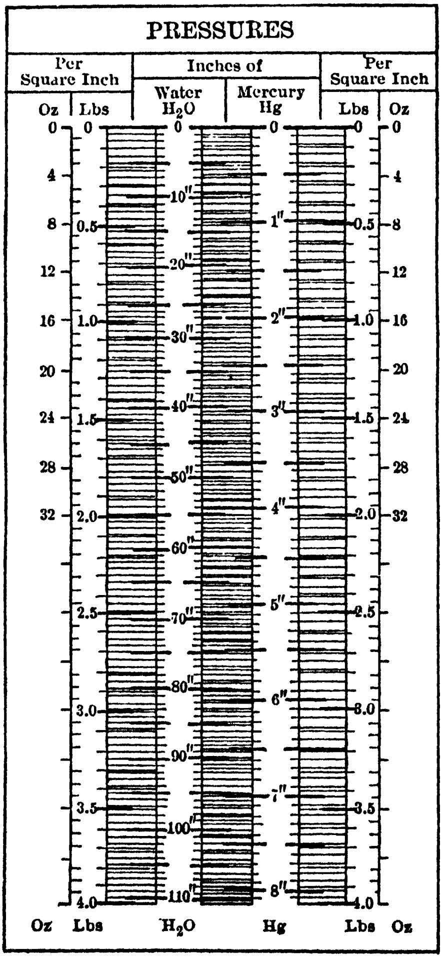
in which P = the pressure in pounds of quiescent water on the surface considered;
A = the area pressed upon in square feet; and
D = the vertical depth in feet of center of gravity of surface considered.

Table I. Pressure in Pounds per Square Inch for Different Heads of Water in Feet

Head, ft	0	1	2	3	4	5	6	7	8	9
0		0 433	0 866	1 299	1 732	2 165	2.598	3 031	3 464	3 897
10	4 330	4 763	5 196	5.629	6 062	6.495	6.928	7.361	7.794	8 227
20	8 660	9.093	9.526	9.959	10 392	10.825	11.258	11 691	12 124	12 557
30	12 990	13 423	13 856	14.289	14.722	15.155	15.588	16.021	16 454	16 887
40	17.320	17 753	18 186	18 619	19 052	19.485	19 918	20.351	20 784	21.217
50	21.650	22 083	22 516	22.949	23 382	23 815	24 248	24 681	25 114	25 547
60	25 980	26 413	26.846	27.279	27.712	28.145	28 578	29.011	29.444	29.877
70	30 310	30 743	31.176	31.609	32 042	32.475	32 908	33.341	33.774	34.207
80	34.640	35.073	35.506	35.939	36.372	36.805	37.238	37.671	38.104	38.537
90	38.970	39.403	39.836	40.269	40.702	41.135	41.568	42.001	42.436	42.867

The pressure for greater heads can be readily found by multiplication or addition; thus, the pressure for a head of 110 ft is ten times that for 11 ft. The pressure for 118 ft is equal to the pressure for 110 ft plus that for 8 ft.

Table II. Pressure Conversion



Pressures of water are measured in inches of water or in inches of mercury. In Table II the corresponding pressures are given in pounds or ounces, inches of water and inches of mercury.

Flow of Water in Pipes. Owing to the many practical and variable conditions which affect the flow of water in pipes, such as the smoothness of the pipe, number and character of the joints, bends and valves in the pipe, to say nothing of the size and length of the pipe, all formulas for the velocity and discharge of water in and through pipes can only be considered as approximate. The following formulas and data are taken largely from the National Tube Company's Book of Standards. They agree fairly well with similar tables by Kent and Trautwine, both of whom devote much space to this subject. The QUANTITY OF WATER passing through a given pipe is governed by the sectional area of the pipe or outlet and the mean VELOCITY. The velocity depends primarily upon the PRESSURE or HEAD, and is greatly affected by FRICTION, which again varies with the smoothness of the bore, the diameter and length of the pipe, and whatever obstructions there may be in the pipe. The HEAD is the vertical distance from the surface of the water in the reservoir to the center of gravity of the lower end of the pipe when the discharge is into the air, or to the level surface of the lower reservoir when the discharge is under water. When the pressure is produced by mechanical means, the head of water in feet may be readily determined by the following table:

Table III.* For Converting Pressure in Pounds per Square In into Head of Water in Feet

Pressure	0	1	2	3	4	5	6	7	8	9

* Tables I and III are exact for water at 62° F. and for atmospheric pressure at 14.7 lb per sq in.

To find the velocity of water discharged from a pipe-line longer than four times its diameter, knowing the head, length and inside diameter, use the following formula:

$$v = m\sqrt{\frac{hd}{L + 54d}}$$

in which v = approximate mean velocity in feet per second;
m = coefficient from the table below;
d = diameter of pipe in feet;
h = total head in feet;
L = total length of line in feet.

The following coefficients are averages deduced from a large number of experiments. In most cases of pipes carefully laid and in fair condition, they should give results varying not more than from 5 to 10%.

Values of Coefficient *m*

$\sqrt{\frac{hd}{L+54d}}$	Diameter of pipe in feet							
	0 05	0 10	0.50	1	1 5	2	3	4

0.20	48	51	55	58	60	64	67	70

Example. Given the head, $h = 50$ ft; the length, $L = 5\,280$ ft and the diameter, $d = 2$ ft; to find the velocity and quantity of discharge.

Substituting these values in the foregoing formula, we get

$$\sqrt{\frac{d \times h}{L + 54\,d}} = \sqrt{\frac{2 \times 50}{5\,280 + 108}} = \sqrt{\frac{100}{5\,388}} = 0.136$$

In column headed $\sqrt{\frac{hd}{L + 54\,d}}$ find 0.10, which is the value nearest to 0.136, and look along this line until column headed 2 is reached; then read 62 as the value of coefficient *m*.

Then $v = 62 \times 0.136 = 8.432$ ft per sec, the velocity required.

To find the discharge in cubic feet per second, multiply this velocity by area of cross-section of pipe in square feet.

Thus, $3.1416 \times (1)^2 \times 8.432 = 26.49$ cu ft per sec.

Since there are 7.48 gal in a cubic foot, the discharge in gallons per second = $26.49 \times 7.48 = 198.2$.

The above formula is only an approximation, since the flow is modified by bends, joints, incrustations, etc.

To find the head in feet necessary to give a stated discharge in cubic feet, use the formula

$$h = \frac{0.000704\,Q^2\,(L + 54\,d)}{d^5}$$

in which h = total head in feet;
L = total length of line in feet;
d = diameter of pipe in feet;
Q = quantity of water in cu ft per second.

Example. Given the diameter of pipe, $d = 0.5$ ft; the length of pipe, $L = 20$ ft; and the quantity of water to be discharged, $q = 3.07$ cu ft per sec; to find the necessary head.

Substituting these values in the above formula, we get

$$h = \frac{0.000704 \times 9.4 \times (20 + 27)}{(0.5)^5}$$

$$= \frac{0.000704 \times 9.4 \times 47}{0.03125} = 9.95 \text{ ft, the required head.}$$

The following formula is simpler and can be used when 54 d in relation to L is so small as to be negligible:

$$h = \frac{0.000704\, Q^2 \times L}{d^5}$$

If the pipe instead of being straight has easy curves (say, with radius not less than five diameters of the pipe) either horizontal or vertical, the discharge will not be materially diminished so long as the total heads and total actual lengths of pipe remain the same, but it is advisable to make the radius as much more than five diameters as can conveniently be done.

To find the diameter of a pipe of given length to deliver a given quantity of water under a given head use the following,

$$d = 0.234 \sqrt[5]{\frac{Q^2 L}{h}}$$

in which d = diameter of pipe in feet;
Q = cubic feet per second delivered;
L = length of line in feet;
h = head in feet.

Example. Given the head, h = 700 ft; the length of pipe, L = 3 000 ft; the quantity to be delivered, Q = 4 cu ft per sec; required the diameter of pipe necessary.

Substituting these values in the foregoing formula, we get:

$$d = 0.234 \sqrt[5]{\frac{16 \times 3\,000}{700}} = 0.234 \sqrt[5]{68.57} = 0.545 \text{ ft} = 6\ 54 \text{ in}$$

To find the diameter of pipe required to deliver a given quantity of water with a given head.

Rule. (1) Reduce the head to feet per 100 ft; (2) from Table IV, find the discharge for the head thus obtained through a pipe 1 ft in diameter; (3) divide the required discharge by that obtained from Table IV; look for the quotient in the column of Table V, headed Ratio of Discharge, etc., and opposite it, in the adjoining columns of the table, will be found the required diameter.

Note. The use of Tables IV and V gives results sufficiently correct for pipes less than 700 diameters in length.

Example. If the head of water from a reservoir to the point of delivery is 20 ft in a distance of 1 860 ft, what is the diameter of a pipe required to deliver 6 cu ft of water per second?

20 ft head in 1 860 ft = 20/18.60 ft in 100 ft, or 1.075 ft in 100.

From Table IV we find that the discharge per second with a head of 1.136 is 3 989 cu ft; for a head of 1.075 it would be about 3.8 cu ft. Dividing the required discharge 6, by 3.8 cu ft per sec, we have 1.58. From Table V the diameter of pipe having a ratio of discharge equal to 1.58 is found to be about 14½ in; therefore we must use a 15-in pipe to obtain the required discharge. If the required discharge is in gallons, divide by 7.5 to reduce to cubic feet. If in cubic feet per minute, divide by 60 to reduce to feet per second.

Table IV. Velocities and Discharges Through a Straight, Smooth Pipe One Foot in Diameter and One Mile, or 5 280 Diameters, in Length

This table shows, also, the relative discharging capacities of long pipes. Thus, one 12-in pipe is equal to two 9-in pipes, to nearly six 6-in pipes, or to thirty-three 3-in pipes.

Table VI. Flow of Water in House Service-Pipes

Thomson Meter Company

To find the discharge in gallons, multiply by 7.47

Condition of discharge	Pressure in main, lb per sq in	Discharge in cubic feet per minute from the pipe — Nominal diameters of iron or lead service-pipe in inches: ½	⅝	¾	1	1½	2	3	4	6

Table VI may also be used when the pressure is in feet-head of water by reducing the head in feet to pounds per square inch by Table I. Thus, if we wish the discharge per minute through a ¾-in pipe 100 ft long with a head of 70 ft, we find from Table I that a head of 70 ft corresponds to a pressure of 30 lb per sq in, and from Table VI we find the discharge thrcugh a ¾-in pipe 100 ft long with a pressure of 30 lb to be 1.84 cu ft per minute.

Table VII. Friction of Water in Pipes Based on Ellis and Howland's Experiments

The following table gives the friction-loss in pounds-pressure per square inch for EACH 100 ft of length in clean iron pipes of different sizes, discharging given quantities of water per minute. This friction-loss is greatly increased by bends or irregularities in the pipe.

To find the friction-head in feet, multiply by 2.3

Gallons per minute	Sizes of pipes, inside diameter							
	¾ in	1 in	1¼ in	1½ in	2 in	2½ in	3 in	4 in
5	3.3	0.84	0.31	0.12

500							30.8	7.43
600								9.54
700								14.32

Friction in the water-supply system is not confined to the pipe and fittings; a proportionately large head is lost driving water through filters and other apparatus. Meters also consume considerable head.

Safe Pressures and Equivalent Heads of Water for Cast-Iron Pipes of Different Sizes and Thicknesses

10	13.0	0.250			

Cast-iron bell and spigot-pipe is known in some localities as CORPORATION PIPE. It is made in four grades, known as Class A, Class B, Class C, and Class D, according to the head or pressure for which it is intended. Class B is the grade most used. Table VIII gives useful information about standard makes of commercial bell and spigot-pipe. The weights are approximate and the weight per foot includes an allowance for the bell. A standard pipe is 12 ft long, although shorter lengths in units of one foot can be had without a bead on the end.

Table VIII. Sizes, Weights and Thickness of Cast-Iron Bell and Spigot-Pipe for Various Pressures

Nominal inside diameter, in	Class A		Class B		Class C		Class D	
	Gas, 100 ft head, 43 lb pressure		Standard, 200 ft head, 86 lb pressure		Medium heavy, 300 ft head, 130 lb pressure		Extra heavy, 400 ft head, 173 lb pressure

Where trench bracing is necessary, allow $3 per linear foot for 100 ft less salvage value of lumber.

For preliminary estimates, Table IX, giving the approximate cost of laying cast-iron water pipes with lead joints, will be found safe as well as convenient. From the table a unit price per foot for each size of pipe can be established and then the totals multiplied by those units.

Private Water-Supply, Pumps

Private Water-Supplies. The architect is frequently required to furnish a water-supply for isolated buildings, and even in cities it is becoming quite common for manufacturing establishments and large buildings to have their own water-supply; so that some knowledge of the various methods of supplying water is requisite. Power-pumps are of so many kinds and so intricate in construction that no attempt will be made to describe them.

The Hydraulic Ram. Where a small stream of water having a fall of 2 ft or more flows near the premises, an hydraulic ram may be used to great advantage to furnish water for domestic purposes, or even for irrigation. The ram is operated by the momentum of the water flowing through the drive-pipe and delivers water into an open tank. Water can be conveyed by a ram 13 000 ft when elevated 500 ft, provided there is sufficient fall. The drive-pipe supplying the ram should be 30 or 40 ft long to give the necessary momentum. The use of the ram is the most economical method of pumping water, as there is no expense for maintenance except for repairs, and the cost of installation, also, is small.

The Capacities of the Rife Rams are given in the following table. The capacities are determined from the table by multiplying the available supply of water per minute, or the rated amount of water a Rife ram will use, by the factor found in the table at the intersection of the line giving the fall available, for the drive-pipe, and the column showing the height the water is to be elevated. The factor for a 10-ft fall and 50-ft discharge is 192, and this multiplied by the supply of water per minute will give the delivery per day. This is shown by the example worked out in the corner of the table. These capacities are based on efficiencies dependent on the ratio of fall to lift. A fall of 10 ft and a lift of 50 ft give a ratio of 1 to 5, and an efficiency of 66⅔%. The efficiencies of Rife rams based on various ratios are also given in the table.

Deep Wells and Plunger-Pumps. The common method of obtaining a private water-supply is to drive a deep well until a sufficient supply of water is obtained. The depth to which a well must be driven will, of course, depend upon the locality, and can only be determined by drillings. As the well is driven, a large wrought-iron pipe is sunk to form the casing. Casings are seldom less than 6 or more than 10 in inside diameter, 8 in being the common size. When the water-pocket has been reached, the water will usually rise and stand in the pipe. The cost of drilling deep wells, per foot of depth, INCLUDING THE CASING, differs, of course, with the strata, location and other local conditions. For raising the water into an open tank a single-acting pump consisting of a working-head, (Fig. 1), which operates a piston located in a cylinder placed in a smaller pipe lowered into the well through which the water is raised is commonly employed. The cylinder should preferably be placed below the water-line in the well, and is usually connected with the working-head by wooden sucker-rods. The working-head may be operated by hand, or by a crank-rod attached to a pumping-jack, windmill or engine. With a single-acting pump the plunger is raised and lowered once with every revolution of

the driving-wheel, the principle of operation being the same as in an ordinary hand suction-pump. Fig. 2 shows a simple arrangement for operating a working-head by belt-power. This is known as a deep-well power working-head. A DEEP-WELL PUMP (Fig. 2) differs from a SUCTION-PUMP in that it will raise water from any depth, whereas a suction-pump in practice will raise water only about 25 ft. A suction-pump may be placed at any point in relation to the well, and will draw the water any reasonable horizontal distance. The deep-well pump, on the other hand, must be set directly over the well, but

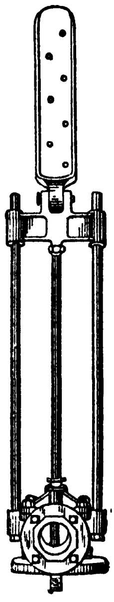

Fig. 1. Working-head for Deep-well Pump

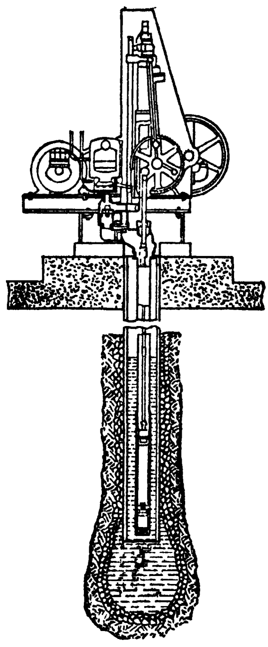

Fig. 2. Deep-well Pump

it will then deliver the water at any desired point. The amount of water pumped in a minute by any single-acting pump is determined by the diameter of the suction-cylinder, the length of stroke, and the number of strokes per minute. The table following gives the capacity per stroke for cylinders of different diameters, and for strokes of different lengths. To find the capacity per minute, multiply the values given in the table by the revolutions per minute. The usual speed of single-acting working-heads and pumping-jacks is from 25 to 30 revolutions per minute. Cylinders over 2¾ in in diameter should have a substantial iron working-head.

Table X. Water Required for Rife Rams

30						..	.	540	465	405	336	288	240	206	180	160	144

Example

With a supply of 1 400 gal. per min. 10-ft fall, 50-ft elevation, No. 120 engine will deliver 268 800 gal per day
$1400 \times 192 = 268800$

* Multiply factor opposite POWER-HEAD and under PUMPING-HEAD by the number of gallons per minute USED by the engine; the result will be the number of gallons DELIVERED per day.

The efficiency developed is governed by the ratio of fall to pumping-head.

The efficiency of rife rams is based on......
- 75% for a ratio of 1 to 2½
- 70% for a ratio of 1 to 3
- 66⅔% for a ratio up to 1 to 18
- 60% for a ratio up to 1 to 23
- 50% for a ratio up to 1 to 30

Table XIII. Action of Wind and Capacities of Pumping Windmills

Velocity per hour in miles	Pressure per square foot in pounds	Description of wind	Action of wind and windmills
3	0.045	Just perceptible. . .	Windmills will not run
5	0.125	Pleasant wind	Might start if lightly loaded
8	0.33	Fresh breeze.	Will start pumping
10	0.5	Average wind. . . .	Pumps nicely if properly loaded
15	1.125	Good working wind .	Does excellent work
20	2	Strong wind. . . .	Gives best service
25	3.125	Very strong wind.	Maximum results secured
30	4.5	Gale.	Should be furled out of wind
40	8	Storm.	Well-constructed mills and towers safe if properly erected
50	12.5	Severe storm	
60	18	Violent storm.	Buildings, trees, etc., might be injured
80	32	Hurricane.	Buildings, trees, etc., would be injured
100	50	Tornado.	Ruin

From the above table it will be seen that the only available winds are those blowing with a velocity of from 8 to 25 miles per hour, and that a 15-mile wind

can be utilized to the best advantage. It is therefore advisable to LOAD a windmill for a 15-mile wind. It then starts pumping in an 8-mile wind, does excellent work in a 15-mile wind and reaches the maximum results in a 25-mile wind.

Table XIV. Capacity of the Windmill

Diameter of mill wheel, ft	Velocity of wind in miles per hour	Revolutions of wheel per minute	Gallons of water raised per minute to an elevation of						Equivalent actual useful h.p. developed
			25 ft	50 ft	75 ft	100 ft	150 ft	200 ft	
8½	16	40 to 50	6 192	3 016					0.04

Windmills. The horse-power of windmills is proportional to the squares of their diameters and inversely as their velocities; for example, a 10-ft mill in a 16-mile breeze will develop 0.15 horse-power at 65 revolutions per minute; and with the same breeze:

a 20-ft mill, at 40 revolutions per minute, 1 horse-power;
a 25-ft mill, at 35 revolutions per minute, 1¾ horse-power;
a 30-ft mill, at 28 revolutions per minute, 3½ horse-power.

The wheels of very few windmills are larger than 25 ft in diameter. There are no pumps which will enable the user of a windmill to utilize the increased power obtained from winds of high velocity, so that in practice the amount of water pumped by windmills in high winds is but little more than is pumped by the same mills in winds having velocities of from 12 to 18 miles per hour. For this reason it is customary to regulate windmills to govern at about 25 miles an hour.

Air-Lift Process. Compressed air is used to an increasing extent for raising water from artesian wells. The process in general consists of submerging a discharge-pipe in a closed well, with a smaller pipe inside delivering compressed air into it at the bottom. The compressed air by its inherent expansive force lifts a column of mingled air and water which is conveyed to an open tank, to permit of the escape of the air. If desired the water may then be conveyed by gravity into a series of closed tanks, and forced by air-pressure to different parts of a building, the only machinery required being an air-compressor and power for driving it. The slip of the bubble constitutes the chief loss of energy in the air-lift. The method of piping a well differs according to its general conditions and the quantity of water to be pumped. "No two wells are alike, and consequently the method of piping which might be applied to one would be unsuited to another."

Advantages of the Air-Lift Process. From two to six times as much water may be obtained from a given diameter of well as with any other known sys-

tem, because there are no valves, cylinders, or rods to hinder the rapid discharge of water. One air-compressor operates any number of wells, which may be any distance apart so as not to affect one another. There is nothing outside the engine-room to look after or wear out. Nothing but common pipe in the wells. Sand or gravel does no harm. The COST of raising 1 000 gal of water by this method, including fuel, labor, oil, interest on cost of well, boiler, compressor, foundations, pipes, real estate, erection and taxes, including 15% for depreciation, runs from 4 cts down to .8 ct, according to the size of the plant, height of lift, and other local conditions. With the average outfit of medium or small size, it is usually under 2½ cts. The air-lift process is now extensively used in ice-works, breweries, cold-storage houses, textile mills, dye-works, etc., and a great variety of industrial plants, and for the water-supply of quite a number of the smaller cities. In Newark, N. J., pumps of this type are at work having a total capacity of 1 000 000 gal daily, lifting water from three 8-in artesian wells.*

Pneumatic Water-Supply Systems. A closed water-tight tank of iron or steel is used with the pneumatic system, and this tank may be located at any level, for the water is forced from it by means of compressed air confined in the top of the tank. This fact makes it possible to bury the tank in the ground below the frost-line, away from the heat of the sun, and where the water will have an almost uniform temperature the year round. The water is protected from possible contamination from insects, rats, birds, dust, or other agencies, while the tank takes up no valuable space above ground, imposes no weight upon the attic-floor of a building, and does not disfigure the landscape. The principle of operation is this: Air is compressible, while water is not. If, then, water is pumped into a closed tank at the bottom, it will trap the air within, and the more water pumped in, the greater the compression of the air. The elasticity of the air, then, will force the water out again, whenever a faucet is opened, and the water will continue to flow as long as the air is under sufficient pressure in the tank. In practice the air would become absorbed by the water in the tank, and in a short time become exhausted, if it were not supplied as fast as used. This is accomplished by injecting a proportionate amount of air with each stroke of the pump, by means of a SNIFTER-VALVE air-compressor, or other device. All connections to the tank are taken from the bottom, to prevent the escape of air which would occur if the connections were taken from the top of the tank.

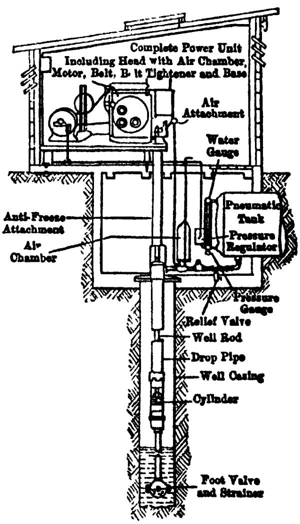

Fig. 3. Typical Installation of Deep-well Pump for Pneumatic Water Supply

A pneumatic system of water-supply used in connection with a deep well is shown in Fig. 3. The pumping-head is located directly over the well for

* Kent.

deep-well pumping, although in shallow-well pumping it may be located at any convenient place not necessarily over the well. In cold climates all parts of the pump containing water are located in a pit below frost-line, an anti-freezing attachment being used for the purpose.

Pneumatic systems are generally operated at pressures varying from 25 to 50 lb. That is, when the pressure of air and water within the tank drops to 25 lb the pump starts automatically and continues pumping until the pressure rises to 50 lb, when the pump automatically cuts out. This range of pressures helps determine the size of tank required.

The following table shows approximately the amount of water that can be drawn from a tank with the pressure starting at 50 lb and dropping to 25 lb, the proportion of air in the tank being $\frac{1}{3}$ to $\frac{2}{3}$ water.

Capacity of tank, gal	Air in tank, gal	Water in tank, gal	Water that can be drawn without pump operating, gal
25	$8\frac{1}{3}$	$16\frac{2}{3}$	5
40	$13\frac{1}{3}$	$26\frac{2}{3}$	8
80	27	53	16
120	40	80	24
220	73	147	44
315	105	210	63
525	175	350	105
1 000	333	666	200

The use of the water likewise helps determine the size of tank to install. For domestic purposes, a comparatively small tank might be desirable to insure frequent changes and keep the water from becoming stale. Where an uninterrupted supply is a necessity, on the other hand, an extra large tank might be desirable to tide over breakdown or repair periods.

Horse-Power Required to Raise Water to Different Heights

General Principles. The power required to raise a certain quantity of water to a certain height varies directly with the quantity to be raised, and also with the height. For instance, it requires twice as much power to raise 200 gal per minute 10 ft high as it does to raise 100 gal to the same height and in the same time; and to raise 100 gal 20 ft high requires twice as much power as it does to raise 100 gal 10 ft high. To find the theoretical horse-power necessary to elevate water to a given height, multiply the number of gallons per minute by 8.335, the weight of 1 gal, and this result by the total number of feet the water is raised, that is, from the surface of the water to the highest point to which the water is raised, and the result gives the power in foot-pounds; divide by 33 000, and the quotient is the horse-power. To the theoretical power a liberal allowance must be made for the inefficiency of the pump. For a cylinder-pump add from 75 to 100%. To the actual height to which the water is to be raised add the friction-loss in feet, given in Table VII, when the discharge is to be piped any distance.

Example. Find the theoretical horse-power required to raise 100 gal per minute 120 ft high, through a 3-in pipe, 200 ft long.

Solution. From Table VII the friction-head for 100 gal per min in a 3-in pipe, 100 ft long, is 1.31×2.3 or 3 ft. For 200 ft it will be 6 ft, which, added to 120, gives 126 ft for the height. Then theoretical horse-power $= 100 \times 8.35 \times 126/33\,000 = 3.2$ h.p. The actual horse-power required will probably vary from 5 to 6, according to the efficiency of the pump. The mistake of using too small a discharge-pipe can easily be seen from Table VII. For instance, if one attempted to force 100 gal per minute through 100 ft of 2-in pipe, the back-pressure would be equivalent to raising the water 22 ft high. The fuel used would be correspondingly increased. Right-angle turns are to be avoided, as the friction is very materially increased, being practically equal to the friction of 25 ft of straight pipe.

Pump Piping. Both the operating economy and the efficiency of a pumping plant depend much upon the manner in which the piping is proportioned and installed. FRICTION is the great power consumer so that suction and discharge lines must be of ample size, as straight as possible and free from unnecessary bends or fittings. Whenever possible LONG RADIUS BENDS are used and GATE-VALVES in preference to GLOBE-VALVES.

When installing suction lines it is well to SLOPE them towards the source of water-supply. The slope permits draining the line and avoids air-pockets.

For reciprocating pumps on long suction-lines an AIR-CHAMBER near the pump is recommended. For any type of pump the suction-line must be tight. If the suction-pipe leaks, air will be drawn in, causing a reciprocating pump to pound and a centrifugal pump to stop pumping and simply churn.

The SUCTION-LIFT of a pump depends upon the temperature of the water to be lifted and its elevation with relation to sea-level. Table XV gives the safe suction-lifts for pumps under various conditions of elevation and temperature.

When a battery of pumps all draw their supply of water from one source, it is advisable to run independent suction-lines to each pump. When the source of supply is above the level of the pump, however, so that water flows to the pumps by gravity, the suctions can all connect to a common header, as is commonly done in practice. Under such conditions each suction-pipe should be VALVED.

Table XV. Safe Suction-Lifts of Pumps

Elevation above sea-level, feet	Atmospheric pressure, pounds per square inch	Barometric pressure, inches of mercury	Temperature of water to be pumped, degrees Fahrenheit				
			60	90	120	150	180
			Safe suction-lift of pumps in feet				
10 000	10.107	20.582	17.0	16.4	14.7	11.3	4.7
5 000	12.224	24.890	20.5	19.9	18.2	14 8	8.2
4 000	12.689	25.837	21.5	20 9	19.2	15.8	9.2
3 000	13.169	26.813	22.4	21 8	20 2	16.8	10.2
2 000	13.665	27.824	23.2	22 6	21 0	17.6	11.0
1 000	14 174	28 861	24.1	23 5	21 9	18.5	11.9
Sea-level	14.696	29.925	25.0	24.4	22.8	19.4	12.8

Water of temperatures higher than 180° F. cannot successfully be raised by suction but for the best operation must flow to the pump by GRAVITY.

Waters of temperatures lower than 180° but over 100° F. can be raised by suction, but are more successfully handled when they flow by gravity to the pumps.

The size of discharge-pipe from a pump affects greatly the cost of operation. A small pipe will cost less to install, but the initial cost will be more than offset by the cost of operation, as the following example shows.

Table XVI. Theoretical Horse-Power Required to Pump Water Through 1 000 Feet of New Pipe

Discharge in gallons per minute	Diameter of discharge pipe in inches							
	1¼	1½	2	2½	3	4	5	6
	Horse-power required							
50	5.4	2.5	0.9					
75		8.0	2.8	0.9				
100		18.3	6.4	2.1	0.9			
150			20.3	7.1	2.9	0.6		
200				15.5	6.3	1.5		
300					20.5	5.0	1.7	
400						11.3	3.8	1.6
500						21.6	7.3	2.9
600							12.2	5.1

Take for comparison a 5-in and a 6-in pipe, each discharging 500 gal of water per minute. The 5-in pipe requires 7.3 theoretical horse-power; the 6-in pipe requires only 2.9 theoretical horse-power.

Assuming a 70% pump efficiency and 86% motor efficiency, the over-all efficiency would be $0.70 \times 0.86 = 0.60 = 60\%$. The actual electrical input to the motors therefore would be 12.1 horse-power for the 5-in pipe and 4.8 horse-power for the 6-in pipe, or 9 and 3.6 kw's, respectively. Based on an 8-hour day and 2 cts per kw hour, the approximate costs for a year would be $540 for the 5-in discharge-pipe and $220 for the 6-in discharge-pipe.

Fire-Streams. The following is an extract from a paper read by John R. Freeman at a meeting of the New England Waterworks Association, entitled Some Experiments and Practical Tables Relating to Fire-Streams: "When unlined linen hose is used the friction or pressure-loss is from 8 to 60%, increasing with the pressure. This kind of hose is best for inside use in short lengths. Mill-hose is better than unlined linen hose for long lengths, but ordinarily the best quality of smooth rubber-lined hose is superior to the mill-hose, having less frictional resistance. The ring-nozzle is inferior to the smooth nozzle and actually delivers less water than the smooth nozzle. For instance, the 7/8-in ring-nozzle discharges the same quantity of water as a 3/4-in smooth nozzle, and a 1-in ring-nozzle the same as a 7/8-in smooth nozzle. Two hundred and fifty gallons per minute is a good standard fire-stream at 80-lb pressure at the hydrant; 100-lb pressure should not be exceeded except for very high buildings or lengths of hose exceeding 300 ft."

Notes on the Construction of Cylindrical Wooden Tanks

Material should be either cedar, cypress, juniper, fir, yellow pine, or white pine, free from imperfections and thoroughly air-dry. Clear Louisiana red, Gulf cypress makes the most durable tanks.

Staves and Bottom of tanks of greater capacities than 15 000 gal should be made of 2½-in, dressed to about 2¼ in, stock for tanks 12 ft and not exceeding 16 ft diameter or 16 ft deep. For larger tanks 3-in, dressed to about 2¾ in, stock should be used. For smaller tanks 2-in stock may be used. Staves should be connected about one-third the distance from the top by a 5/8-in dowel to hold them in position during erection. The bottom planks should be dressed on four sides, and the edges of each plank should be bored with holes not over 3 ft apart for 5/8-in dowels.

Taper. The batter to each side should not be less than ¼ in nor more than ½ in per ft.

Hoops should be of ROUND wrought iron or mild steel of good quality. Wrought iron is preferable because it does not rust as easily as steel. There should be no welds in any of the hoops. Where more than one length of iron is necessary, lugs should be used to make the joints; and when more than one piece is necessary the several pieces constituting one hoop should be tied together in preparing for shipment. Hoops for fire-tanks should be of such size and spacing that the stress in no hoop will exceed 12 500 lb per sq in when computed from the area at root of thread. For general purposes, a stress of 15 000 lb per sq in is permissible. On account of the swelling of the bottom planks, the hoops near the bottom may be subjected to a stress greater than that due to the water-pressure alone; additional hoops, therefore, should be provided. For tanks up to 20 ft in diameter, one hoop of the size used next above it should be placed around the bottom opposite the croze and not counted upon as with standing any water-pressure. For tanks 20 ft or more in diameter, two hoops, as above, should be used. Hoops with UPSET ends must not be used. The top hoop should be placed within 2 in of the top of staves, so that the overflow-pipe may be inserted as high as possible. Hoops should be so placed that the lugs will not be in a vertical line. No hoop should be less than ¾ in in diameter. All should be cleaned of mill-scale and rust and painted one coat of red lead, lampblack and boiled oil before erecting.

Note. The strength of a tank depends chiefly on its hoops. Round hoops are specified because they do not rust rapidly; a slight amount of rust does

not have the same weakening effect as on a flat hoop, and round hoops are not likely to burst when the tank swells, as they will sink into the wood.

Spacing of Hoops. The hoops should be spaced so that each one will have the same stress per square inch, and no space should be greater than 21 in. To meet this requirement the hoops must be spaced quite close together at the bottom, the space between them gradually increasing towards the top.

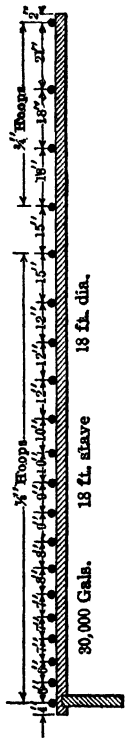

Fig. 4. Diagram of Hoop-spacing for Tanks

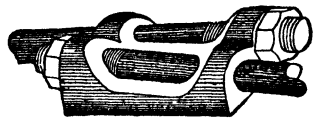
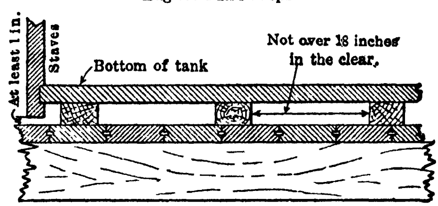


Lug for Tank-hoops



Support for Bottom of Tank

Fig. 5. Wooden Tank Details

Fig. 4 shows the proper spacing of hoops for a tank 18 ft in diameter, with 18-ft staves. The spacing for seven other sizes of tanks is given in the pamphlet referred to. It may be computed by the following formula:

$$\text{Spacing of hoops in inches} = \frac{\text{strength}}{2\ 6 \times \text{diameter in feet} \times H}$$

For strength of a $\frac{3}{4}$ 9-in rod use 3 750; of a $\frac{7}{8}$-in rod, 5 250; of a 1-in rod, 6 875; and of a $1\frac{1}{8}$-in rod, 8 625.

H is the distance from surface of the water to center of hoop in feet.

Example. How far apart should 1-in hoops be placed, at 15 ft 2 in from top of tank, on a tank 20-ft diameter?

$$\textbf{Solution.}\quad \text{Spacing} = \frac{6\ 875}{2.6 \times 20 \times 15} = 8\tfrac{3}{4}\ \text{in}$$

Lugs should be as strong as the hoops. A lug similar to Fig. 4 is simple and fulfils the requirement for strength. Malleable lugs are required.

Support. The weight of the tank should be supported entirely from its bottom; and in no event should any weight come on the bottom of the staves. The planks upon which the tank-bottom rests should cover at least one-fifth the area of the bottom, should be not over 18 in apart, and of such thickness that the bottom of the staves will be at least 1 in from the floor (see Fig. 5).

The Discharge-Pipe should preferably leave the bottom of the tank at its center and extend up inside of the tank 4 in, to allow the sediment to collect in the bottom of the tank.

The Overflow-Pipe should be placed as near the top of the tank as possible, discharging either through side or bottom, as may be desired. An overflow is much to be preferred to a telltale, as the latter is liable to get out of order.

Heating. Tanks of moderate size need to be provided with some means to prevent freezing. When a tank is in an enclosed room, as in a mill-tower, the best method is to keep the room warm by a coil of steam-pipe with a return to the boiler-room. A covered tank out of doors may often be similarly heated by placing the steam-pipe in the bottom of the tank. With a tank located on a high trestle, or at a distance from the steam-supply, it is often impracticable to arrange a return-pipe. In this case steam may be blown directly into the water in the tank. A 1-in pipe is generally sufficient for this purpose. It should be carried to the top of the tank and there bend over and dip downwards, so that its outlet is about 1 ft below the high-water line. A check-valve should be placed in this steam-pipe, near its point of discharge, to prevent water being drawn back by siphon-action when the steam is shut off. The water in fire tanks must be kept from freezing by means of a water-heater which either heats a coil in the tank, or circulates a current of water through the tank.

Frostproofing for Pipes. The discharge-pipe from a tank on a trestle, or from one elevated above a roof, must be protected from freezing. The common practice is to enclose the pipe in a double, triple, or quadruple box made of boards and tarred paper, as shown in Fig. 6. If steam is supplied to the tank, the steam-pipe is carried inside the box. In New England, New York State and Canada the quadruple boxing is generally used, whereas in the milder regions to the south triple or double boxing is used. The boxing should always be carried down into the ground below the frost-line, and a good tight joint made at the underside of the tank.

Fig. 6. Method of Frostproofing Pipes

Covers. For economy in heating and to prevent birds, leaves, etc., from getting into the water, all out-of-door tanks should be covered. A double cover is recommended consisting of a tight flat cover made of matched boards supported by joists which span the top of the tank, and above this a shingled, conical roof. To prevent the covering from being blown off, it should be firmly fastened to the top of the tank by straps of iron. In order to keep out the wind particular attention should be given to making a tight joint where the roof rests on the top of the staves.

Scuttles should be arranged in both the conical and flat covers to give access to the inside of the tank and a substantial, permanent ladder erected to give easy access to the top of the tank.

Table XVIII. Dimensions of Tanks of Standard Sizes

20	12	16	2¾ to 1	6	1 500	1 655	200	50	60	160

Capacity of Standard Fire Pump Sizes. Plunger-diameter alone will not tell how many gallons per minute a pump can deliver, and it is not reasonable to continue the oldtime notion of estimating capacity on the basis of 100 ft per minute piston travel.

Careful experiments on a large number of pumps of various makes at full speed show that in a new pump with clean valves, and an air-tight suction-pipe, and less than 15-ft lift, the actual delivery is only from 1½ to 5% less than plunger-displacement. This slip will increase with wear, and for a good average pump in practical use, probably 10% is a fair allowance to cover slip, valve leakage and slight short-stroke.

Largely from tests, but partly from practical experience and recognizing that a long-stroke pump can run at a higher rate of piston travel in linear feet per minute than a short-stroke pump, and that a small pump can make more strokes per minute than a very large one, the speeds given in Table XIX have been adopted as STANDARDS IN FIRE SERVICE for direct acting (non-fly-wheel) steam-pumps, which have the large steam and water passages herein noted.

National Board of Fire Underwriters' Suggestions for Centrifugal Fire-Pumps and Steam-Driven Pumps

"**The centrifugal pump** is well adapted for driving by an ELECTRIC MOTOR or by a STEAM TURBINE, as the speed of the pump and the prime mover may readily be made the same, thus permitting direct connection. Whether or not the motor drive may be accepted in any case is largely a question of the reliability of the electric current in the event of a fire in the property itself or in adjoining buildings which might threaten the property. To make a motor-driven pump acceptable, the electric power supply should be as reliable as the steam-supply on the average property for the ordinary steam fire-pump. Each case must therefore be specially considered and decided upon its merits. Other methods of driving, such as the GASOLINE ENGINE or the STEAM TURBINE, may be employed, and where reliable will be acceptable.

"Pump equipment to be satisfactory shall furnish its rated capacity at the top sprinklers at a working pressure of at least 25 lb; when hose streams are to be supplied, the pump should furnish rated capacity at not less than 100 lb total discharge pressure, and at least 50 lb at the topmost 2½-in standpipe outlet or most remote 2½-in hydrant outlet, while water is being discharged through 50 ft of 2½-in cotton rubber-lined hose, and 1⅛-in nozzle."

The six standard centrifugal pumps are the 500-gal, 750-gal, 1 000-gal, 1 500-gal, 2 000-gal, and 2 500-gal sizes. The rated speed of those pumps will be about as follows:

Electric-motor driven	1 800 r.p.m.
Steam-turbine driven	2 500 r.p.m.
Gasoline-engine driven	1 600 r.p.m.
Chain driven	900 r.p.m.

Steam-Driven Pumps. "The BOILER-POWER is that required for continuous running at full speed and pressure. It is, however, often best to put in a larger pump than the existing boilers could drive at full capacity, as a small boiler will drive a 750-gal pump at the 500-gal speed with very nearly as much economy as it can drive a 500-gal pump at full speed. The pump then does not have to be changed when the plant is enlarged and the boiler-power increased.

"It is proper to run fire-pumps at the highest speed that is possible without causing violent jar or hammering within the cylinders. Considerations of

wear do not affect the brief periods of fire service or test, hence these speeds are greater than allowable for constant daily duty.

"AIR and VACUUM-CHAMBERS in accordance with the sizes given in the following table must be provided with all pumps. If the air-chamber is of cast iron, the pump manufacturer must warrant that it has been subjected to a hydraulic test of 400 lb per sq in before it is connected to the pump."

Size of Vacuum and Air Chambers

Capacity of pump, gallons per minute	Vacuum-chamber is to contain	Air-chamber is to contain
500	13 gal	17 gal
750	18 gal	25 gal
1 000	24 gal	30 gal
1 500	30 gal	40 gal

House Tanks. House tanks for large buildings may be divided into SUCTION-TANKS and STORAGE-TANKS. Suction-tanks may be either cylindrical and closed or rectangular and open. Storage or supply-tanks are generally rectangular and open, but provided with a cover.

Cylindrical tanks are as a rule built with heads dished out. The radius of the dished heads is equal to the diameter of the tanks.

For tanks up to 36 in in diameter the heads are made of steel 1/16 in thicker than the shell-plates. Tanks of from 36 to 96 in in diameter have heads 1/8 in thicker than the shells. Tanks of greater diameter than 96 in have heads 1/4 in thicker than the shells.

Sometimes a cylindrical tank is made with one head dished in. When that is the case, for diameters up to 72 in, the dished-in head is made 1/8 in thicker than if it were dished out. For diameters from 72 to 96 in the dished-in head is increased in thickness 1/4 in. Above 96 in in diameter reversed heads should not be used.

The FORCE TENDING TO DISRUPT a cylindrical tank is the internal unit pressure acting over the diameter, or projected area, of the tank. Opposed to that force is the STRENGTH OR THICKNESS OF METAL in the two sides of the tank.

The INTENSITIES OF STRESSES in lb per sq in found in water towers are as follows: A tensile stress due to hydrostatic pressure at any vertical joint or section of the shell of a tank filled with water,

$$S = 62.5\,HD/(2 \times 12\,t) = 2.6\,HD/t$$

A compressive stress at any horizontal joint or section, due to the weight of the stack,

$$S = W/(\pi D \times 12\,t) = 0.026\,W/Dt$$

A stress at any horizontal joint or section, tensile on the windward side and compressive on the leeward side, due to the wind, $S_2 = 0.106\,M/D^2t$. In the above equation, H = height of tank in ft above section considered, D = diameter in ft, t = thickness of shell in in, W = weight of tank in lb, and M = bending moment in ft-lb. The conditions for overturning from wind are most severe when the tank is empty.

Rectangular house tanks have condensation-pans usually of 1/16 in steel, 4 in deep, extending 6 in outside of the tank. A condensation-pan 4 in deep requires no top-edge stiffening. The tank is provided with an iron ladder and, if 6 ft or under, is generally made of 1/4-in plates; if from 6 to 8 ft deep, 5/16-in plates; from 8 to 10 ft deep, 3/8-in plates.

Tanks are ELEVATED a distance of about 18 in by means of I beams resting

on the condensation-pan. This gives access to the bottom of the tank for painting and provides the necessary space for pipe-connections.

House tanks should be painted both inside and outside with Bitumastic or some similar solution applied while hot. The condensation pan should be treated to a like coat to prevent rusting.

BRACES of $2\frac{1}{2} \times \frac{1}{16}$-in steel on edge are used as tie-rods to stiffen a rectangular tank and an angle iron is used as a top-edge stiffener.

2. Plumbing and Drainage

Definitions of Terms

HOUSE-SEWER is that portion of the drainage system extending from the building line to the street-sewer.

HOUSE-DRAIN is the system of horizontal piping inside the building that extends to and connects with the house-sewer. All soil, waste and leader stacks, also yard, area and sometimes floor-drains are connected to the house-drain.

STACKS are the vertical lines of soil, waste and vent-pipes which extend from the house-drain up to and through the roof. Up to the highest fixture on the line drainage pipes conveying fluids are either SOIL or WASTE-STACKS. Above the highest fixture they become VENT-STACKS.

SOIL-STACKS are the vertical lines which receive the discharge from water-closets. Soil-stacks may, and generally do, receive the discharge from other fixtures also, such as from lavatories, sinks or bath-tubs.

WASTE-STACKS are the vertical lines which receive the discharge of fixtures other than water-closets.

VENT-STACKS receive no discharges. They supply the drainage system with air to prevent syphonage of traps, and relieve pressure within the system. A vent-stack accompanies every soil or waste-stack. The vent-stack is connected to the base of the accompanying stack by means of a "Y" below the lowest fixture, and to the upper part of the stack above the highest fixture by means of a "T" fitting, or it may extend independently through the roof. When a vent-stack is connected to a soil or waste-stack above the highest fixture discharging into the line, from that point to the roof the continuation is known as a VENT-STACK.

SOIL-PIPE is the system of piping at the various floors which connects water-closets to the soil-stack.

WASTE-PIPE is the system of piping at the various floors which connects fixtures other than water-closets to the soil or waste-stack or to a soil-pipe.

VENT-PIPE is the system of piping at the various floors which connects the soil or waste-pipe to the corresponding vent-stacks.

TRAPS. A trap is a device which permits the free passage of liquids through it, and also of any solid matters that may be carried by the liquid, while at the same time preventing the passage of air or gas in either direction. Traps used for plumbing purposes are shaped so that an amount of water sufficient to close the passage and prevent the passage of air will stand in them at all times. The principle of the common trap is shown in Fig. 7. The pipe T receives the waste from a sink or lavatory, while the lower end B connects with the drainage system. Sewer-gas rises in pipe B, but is prevented from passing to the fixture by the water which stands in the trap. The depth of water through which gas must pass to effect a passage is termed the WATER-SEAL. The water-seal in the trap, Fig. 7, is the distance S. All plumbing-pipes which connect with a drainage-system require to be trapped to prevent

sewer-gas from passing through them into the room in which the fixture is located.

Ventilation of Traps. When a considerable volume of water rushes down a pipe it forms a suction, and if the pipe is made air-tight, this suction

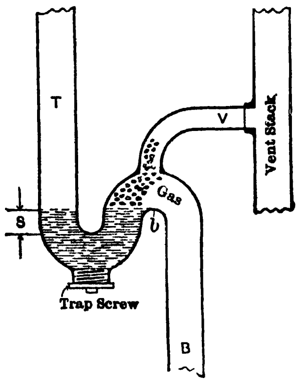

Fig. 7. Water-seal of Trap

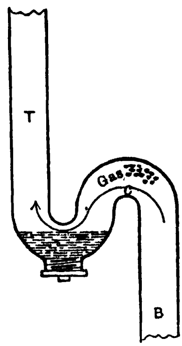

Fig. 8. Water-trap Unsealed

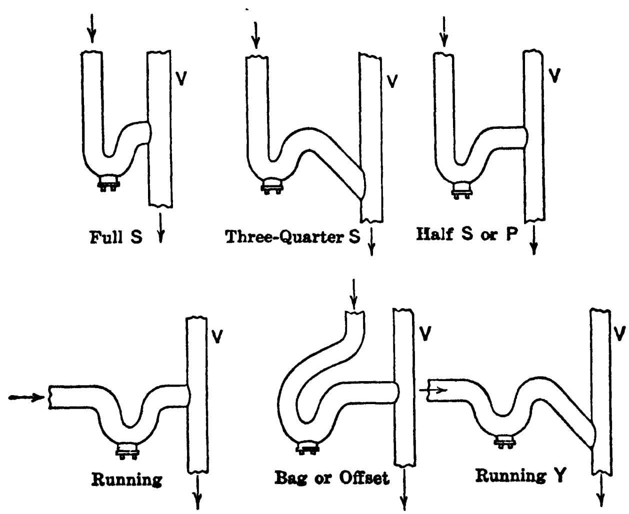

Fig. 9. Types of Traps

is often sufficient to prevent enough water remaining in the trap to form a seal, thus leaving an opening for the passage of sewer-gas, as in Fig. 8. By connecting the upper bend of a trap with the outside air by means of a pipe, as at *V*, Fig. 7, syphonic action will be broken, and the water in the pipe *T* will

not fall below the level of the outlet at *b*. There are also several varieties of back-pressure traps, designed to prevent the sewage from flowing back into the house-drain. These are in the nature of check-valves, and are used principally in seaport-towns where tide-water might possibly force the sewage back.

The more common shapes of lead traps used in plumbing, with their trade names, are shown in Fig. 9. The same shapes are also made of cast iron and brass. The pipes marked *V* are the vent-connections. The traps for water-closets are commonly formed in the fixture.

Drainage System

The various parts of a drainage system are shown in Fig. 10. That portion of the horizontal drain extending from the street-sewer to within a few feet of the foundation wall of a building is the HOUSE-SEWER. Continuation of this horizontal drain within the building is the MAIN HOUSE-DRAIN. Just inside of the foundation wall is the MAIN DRAIN-TRAP and a FRESH-AIR INLET leading to the atmosphere outside.

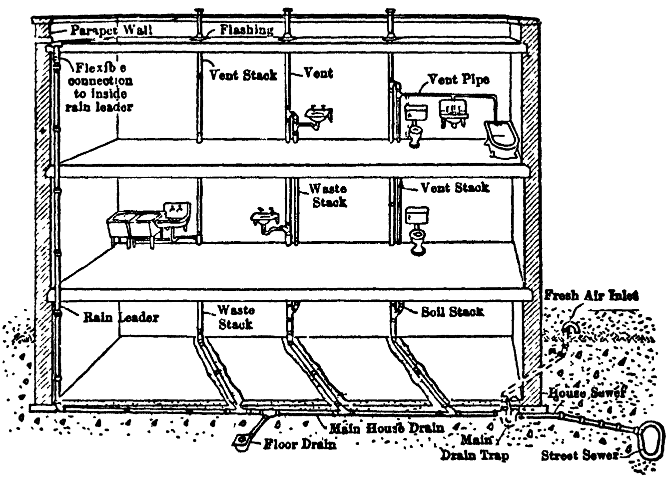

Fig. 10. Drainage System for a Residence

A FLOOR-DRAIN is shown in the cellar floor. Floor-drains are advisable only where a water-seal in the trap will be assured. Unless water is to be splashed, poured or spilled on a floor it is better to omit the floor drain or run the waste into a rain-leader, yard or area-drain on the house side of the trap. Rain-water will then insure the trap being sealed.

Branches to waste and soil lines are taken off with Y or T-Y fittings. If the runs are horizontal, long turn or long radius T-Y's are used. Short turn T-Y's are permissible for vertical stacks.

All vertical stacks extend through the roof where they open to the atmosphere. This enables air to circulate through the system, tending to keep the pipes free from the accumulation of objectionable odors or gases.

Materials for the Drainage System. The drainage system is made up of CAST-IRON SOIL-PIPE, GALVANIZED WROUGHT IRON, STEEL or LEAD PIPE. LEAD PIPE is now used principally for short connections between water-closets and soil-pipe. Sometimes it is used for other fixture connections. The lead pipe usually used in a drainage system is known as D pipe, and has the following weights per linear foot:

Table XX. Weight of Lead Pipe

Inside diameter of pipe	Weight per foot
1¼-in pipe	2½ pounds
1½-in pipe	3 pounds
2-in pipe	4 pounds
3-in pipe	6 pounds
4-in pipe	8 pounds

CAST-IRON SOIL-PIPE is commonly used for the house-drain, stacks of soil, waste, vent, and leader-lines in buildings of moderate height. In the tall steel skeleton type of building, cast-iron soil-pipe is used for all underground work, and galvanized iron or steel pipe with recessed drainage fittings for the soil, waste, and leader-stacks. Ordinary galvanized fittings are used on the vent-stacks.

Cast-iron hub and spigot-pipe is made in two grades or weights, known as STANDARD and EXTRA HEAVY. Extra heavy soil-pipe is used in the better grade of buildings. The weights of various sizes of soil pipe and their fittings are given in Table XXI.

Standard-weight GALVANIZED WROUGHT IRON or STEEL PIPE is also used for drainage-pipe.

Proportions of the Drainage System. The main house-drain and the house-sewer are preferably of one size. In cities having plumbing laws or regulations, the size of house-drain is given in the code. Where there are no regulations the house-sewer and house-drain are determined by the volume of sewage to be handled.

When rain-water discharges into the drainage-system the volume of rain-water is so much greater than the volume of domestic sewage that ordinarily if the sewers are large enough to take care of the rainfall they will be big enough for domestic purposes. In exceptional cases the domestic sewage might have to be added to the rainfall in determining the volume of liquid to be cared for. It is seldom that rain falls at a greater rate than 6 in per hour, and that for a period not longer than ten minutes at a time.

Table XXII gives the precipitation in various parts of the United States.

* Compiled by the Weather Bureau from records covering a long term of years.

In Table XXIII can be found the areas of roof or other pitched surface that can be cared for by house-drains of various diameters laid at given grades. The areas given are conservative.

Table XXIII. Size of House-Drains

Diameter of drain, inches	Areas the pipes will drain when laid at grades of	
	¼ inch per foot	½ inch per foot
3	1 200 sq ft	1 500 sq ft
4	2 500 sq ft	3 200 sq ft
5	4 500 sq ft	6 000 sq ft
6	8 000 sq ft	10 000 sq ft
7	12 400 sq ft	15 000 sq ft
8	18 000 sq ft	22 500 sq ft
9	25 000 sq ft	31 500 sq ft
10	41 000 sq ft	59 000 sq ft
12	69 000 sq ft	98 000 sq ft

When the volume of sewage added to the rainfall is large, the size of house-sewer and house-drain can be determined by this empirical rule:

Rule. Allow 1 sq in in sectional area of the drain for each 2 cu ft or 15 gal of sewage to be discharged per minute.

Table XXIV. Carrying Capacity of Sewer-Pipe

Gallons per minute

Size of pipe, in	Fall per 100 ft

Rain-Leaders are preferably not smaller than 2½ in in diameter. Smaller pipes are liable to clog with leaves. They are never larger than 8 in in diameter, for when an area requires a large leader it is better to provide several leaders of smaller diameters.

Size of Leaders. The Barrett Company, from their extensive experience in roofing, sum up their conclusions in the two following paragraphs and Table XXVI of leader sizes:

"For roof-areas of more than 4 000 sq ft, it is considered the best practice to drain to different points, using smaller leaders, rather than to one outlet of larger size, although in some cases the arrangement of leader-lines makes the latter method compulsory.

"A standard table not always being available, an easy and reliable formula to use is as follows: For roofs covered with gravel or slag, with an incline not exceeding ¼ in per ft, allow 300 sq ft of roof-surface to each square inch of leader opening; for roofs of greater incline or saw-tooth roof-construction, allow 250 sq ft of roof-surface to each square inch of leader opening; for metal, tile, slate or similar roofs of any incline, allow 200 sq ft of roof-surface to each square inch of leader opening. Table XXVI can be depended upon in estimating roof drainage, it being based on the heaviest storm conditions recorded."

Table XXVI. Size of Leaders

Kind of roof	Diameter of leader in inches					
	2½	3	4	5	6	8
	Square feet the leader will drain					
Covered with gravel, slag or other similar material with incline ¼ in in 1 ft	1 800	1 800 to 2 200	2 200 to 3 600	3 600 to 5 600	5 600 to 8 000	8 000 to 14 000
Same, with incline ½ in or more in 1 ft, and saw-tooth	1 200	1 200 to 1 700	1 700 to 3 100	3 100 to 4 900	4 900 to 7 000	7 000 to 12 000
Metal, tile, slate or similar roofs of any incline	1 000	1 000 to 1 400	1 400 to 2 500	2 500 to 3 900	3 900 to 5 600	5 600 to 10 000

In the densely built-up districts of many cities the public sewers are overtaxed during heavy rainstorms, and water from the sewers backs up into the lower floors of the building through the plumbing fixtures. It is well, therefore, when planning the plumbing for a large building of any kind subject to this flood condition, to discharge all fixtures on the ground floor as well as those at a lower level into a SEWAGE EJECTOR. If for any reason this cannot be done, a BACK-WATER TRAP should be installed in the main house-drain, and a quick-closing lever handle valve installed next to the back-water trap so it can be shut in case of threatened flood.

Materials for Industrial Wastes. In chemical laboratories, chemical works, storage-battery rooms, dye-works and in buildings used for other industrial purposes, the waste fluids are often of such a nature that they will corrode and destroy in a very short time the usual materials of a drainage system.

There are three chemical-resisting materials on the market made up into pipe and fittings with which a drainage system can be installed. They are HIGH-SILICON CAST-IRON pipe and fittings; FIBER CONDUIT; and INDURATED RUBBER.

DURIRON is a commercial example of high-silicon pipe. It is a cast metal, extremely hard and close grained. Owing to its high percentage of silicon, 14.5%, Duriron is very brittle, taking on some of the properties of glass, so it has to be worked and handled with care. Even when calking, the danger of cracking a hub is great unless the lead is calked with great care. The pipe is easily cut with an ordinary pipe-cutter. Duriron soil-pipe and fittings can be had in all sizes of ordinary extra-heavy cast-iron pipe; also a special size 1½ in in diameter with fittings to match may be had. The pipes are put together with a lead-calked joint, but instead of oakum, asbestos rope is used as a packing Duriron floor-drains, sinks, vats, kettles and other acid-resisting containers are also made. High-silica pipe and fittings will resist all commercial acids, but will not withstand the destructive effect of sodas or other alkalies

Lead pipe has been used to some extent for acid wastes, as have also lead-lined iron pipes. Lead is suitable for only a few acids, however, and there is a weak spot at every joint of lead-lined iron pipe and where lead pipes are joined, unless the lead is burned, not soldered. Concentrated nitric acid will completely dissolve lead pipe in a short time, while concentrated hydrochloric acid will destroy lead pipe in a couple of years.

FIBER CONDUIT, made up in the form of pipe and fittings, is used in chemical laboratories and industrial works where both acid and alkaline wastes have to be taken care of. The fiber conduit is resistant to almost every waste encountered in industry.

INDURATED RUBBER is made up in the form of pipe, fittings and valves. There are many places where rubber supply-pipes, pumps and wastes are preferable to either metal or fiber conduits.

Water Consumed in Buildings

Estimate of Water Needed. If the amount of water that would be required in a new building were known, it would be a simple matter to proportion the piping to supply the necessary quantity. As a guide in estimating the water-supply for a building the following tables will prove helpful. In Table XXVIII is given the average amount of water used per day in several well-known New York hotels and office-buildings. The cubes of the building are given, the number of occupants and the number of plumbing fixtures.

Table XXVIII. Consumption of Water in Hotels and Office Buildings

Building	Cube in feet	Number of occupants	Number of bath-rooms	Number of plumbing fixtures	Water used per day, gal (average)	Storage capacity section-tank, gal	House pumps
Ritz-Carlton... ..	3 746 373	900 guests 300 employees*	428	1 617	270 000	15 000	2—150 g p m
N. Y. Ambassador	4 680 290	800 guests 265 employees	366	1 288	270 000	26 000	2 Worthington, 5¼×3½
Equitable Building (120 Broadway)	24 918 736	12 000 tenants	.	1 500 approx	105 905	50 000	8 Worthington: 4—14×20–9½×18 2—10×17–8½×15 2— 9×14–8½×15
Woolworth Building...	13 110 942	12 000 tenants	..	2 300 approx	175 905	88 000	8 pumps, combined capacity 2 000 g p m; average 250 g p m
Municipal Building. .	19 000 000	4 363 tenants	..	.	254 737	68 000	3—500 g p m, 400 ft head; 2—300 g p m 600 ft head

* Number of employees assumed, allowing one employee to three guests.

In the case of hotels, the cube seems to bear no relation to the water-consumption. nor does the number of fixtures installed. The NUMBER OF OCCUPANTS bears a reasonable relation, however, the water-consumption in one of the hotels listed averaging 225 gal per occupant per day, while the average daily consumption in the second hotel was approximately 250 gal per occupant per day. In both of the hotels steam turbine generators were installed which required water for condensation. As 20 to 30 gal of water are required to condense $8\frac{1}{3}$ lb of steam, the per capita consumption would be cut down considerably where current is obtained from the public service corporation.

In the case of the two office-buildings tabulated, each having the same tenancy, there is seemingly a great difference in the amount of water consumed per day. However, while both buildings have a large number of non-tenants visiting them daily, the Woolworth has the larger number because of its law school and sight-seers. These swell the total water-consumption.

The Municipal Building shows up even better than the Woolworth the difference in the water-consumption due to tenants, and that due to callers. The Municipal Building has only two-thirds the tenants of either of the two other buildings, still the water-consumption is much greater. This is largely due to the number of people having business with the City Departments who flock to the Municipal Building every day throughout the year.

When an office-building is erected it is impossible to foretell what the occupancy will be, therefore the water-supply must be large enough to take care of the maximum demand.

In some of the larger cities the quality of the water supplied is such that TUBURCULATION takes place inside of the pipes, or there may be CORROSION and a partial clogging from rust. In such localities an additional area must be provided in the water-pipes to allow for loss of capacity, or pipes of materials that will not be affected by the water must be used.

The MONTHLY TOTALS of water consumed do not vary much in large buildings throughout the year. This is shown by Table XXIX, giving the water-consumption for one year in the Woolworth Building and the Municipal Building. Readings in the Municipal Building were taken three times a month, approximately every ten days.

More important than the daily, monthly or yearly consumption of water, from a pipe-size standpoint, is the HOURLY RATE OF FLOW of water. It is found in large office-buildings that there are two periods of excess consumption. One is from 9:00 to 10:00 A.M., just after the tenants arrive; the other during the noon-hour. In the Municipal Building it was found that the average daily consumption of water was 33 965 cu ft, while the hourly consumption between 9:00 and 10.00 A.M. was 1 690 cu ft, or about one-twentieth the average daily consumption.

The water-supply for a building must be proportioned to take care of the maximum demand while at the same time maintaining a reasonable reserve capacity for a still further demand. When considering the maximum demand the occupancy of a building must be considered. A study of the foregoing tables will show that in two buildings of the same class having an equal number of tenants, the difference in occupancy increased the water-consumption over 66% in one building, while compared with a public building the difference in consumption was almost as 1 to 7.

Supply-Pipes. The materials best suited for water supply-pipes can be determined only in the localities where they are to be installed. No set rule or law can be laid down that will be right in all cases. There are some localities where LEAD pipes are destroyed in a very short time on account of the

chemical composition of earth or water. In other localities BRASS pipes will not stand up under use. Still other localities are extremely hard on IRON and STEEL whether GALVANIZED or PLAIN. The only rule therefore is the LAW OF EXPERIENCE. Brass and galvanized wrought-iron or steel are the materials commonly used. Lead pipe is used in some localities, while block-tin pipe is used for soda-fountain work, beer pump-lines and for conducting chemical preparations in industrial plants.

Designation of Lead Pipe. The different thicknesses of lead pipe were formerly designated by letters as in Table XXXI, but are now more commonly designated as in Table XXX, which may be considered as generally accepted by dealers.

Coils of supply-pipe weigh about 200 lb; aqueduct about 90 lb; suction-pipe, 100 to 180 lb each.

Block-tin pipe is stronger for a given weight per foot than lead pipe or tin-lined lead pipe. As compared with lead pipe its strength is as 3½ to 1.

Tin-lined and lead-lined iron pipe is made with inside diameters of ½, ¾, 1

Water Required for Various Purposes. For sprinkling 100 sq ft of lawn, about 1 cu ft, or 7 to 8 gal. For soaking 100 sq ft of lawn, about 2½ cu ft, or from 15 to 16 gal.

To flush closets, 5 to 6 gal at each flush. The actual rate of discharge from water-closets is about 1¼ gal per second. To fill the bowl of an ordinary lavatory, about 1½ gal. To fill a bath-tub, about 20 gal. Only about 8 gal are used for a bath.

Table XXXII. Weight and Sizes of Pure Block-Tin Pipe

5/8	9, 12, 16	....	....

The consumption of water by farm animals varies greatly, depending upon the season of the year, the age and individual habits of the animals. The following can be accepted as extremes: Horse, 5 to 10 gal per day; cattle, 7 to 12 gal per day; hogs, 1½ to 2½ gal per day; sheep, 1 to 2 gal per day.

For mixing concrete 6 to 8 gal of water are required for each 94-lb sack of cement.

Each developed boiler horse-power requires 34.5 lb or 4.1 gal of water.

Compound engines will develop an engine horse-power on 15 lb of water evaporated to steam.

Single condensing engines will develop an engine horse-power on 18 to 22 lb of water.

Automatic non-condensing engines will develop an engine horse-power on 28 to 32 lb of water.

A side-valve throttle-governing engine will develop an engine horse-power on 62½ lb or 1 cu ft of water.

Locomotives average a consumption of 3 000 gal of water for every 100 miles

Forty to 60 lb of condensing water are required for each lb of steam condensed to moderate temperature; 60 to 100 lb of water per lb of steam when the water used is at the higher temperature common to cooling-tower practice.

Consumption of water in military camps is about 10 gal per capita daily.

Equation of Pipes. In a water-supply distributing system numerous branches are taken off from the main lines. The question which rises constantly is, "How many branches can be supplied by the main?". The number can be determined by Table XXXIII.

The statement is often made that doubling the diameter of a pipe increases its capacity four times. That statement, however, is only partly true. At the same velocities of flow, doubling the diameter of a pipe increases its capacity four times. But the same head or pressure will produce different velocities in pipes of different sizes or lengths, and doubling the diameter of a pipe when the pressure remains constant increases the capacity of the pipe almost six times.

In Table XXXIII figures above the diagonal line refer to standard-weight wrought-iron and steel pipes, the diameters of which vary a little from the actual diameters given. In the lower part of the table the figures refer to pipes of the actual sizes given. Extra strong and double extra strong pipes have smaller bores than those of standard wrought-iron pipes. The outside diameters of all pipes of corresponding sizes are the same for threading standardization. As the walls of the extra strong and double extra strong pipes are thicker, the pipe bores are of necessity smaller.

Actual Internal Diameters

Use of Table XXXIII. The table is used in the following manner. If it is desired to know the number of ¾-in pipes that will equal in discharging capacity a 2-in pipe, glance down the column headed 2 to the intersection of the line in the first column marked ¾. This shows that it requires fourteen ¾-in pipes to equal one 2-in pipe.

To find the number of pipes of one size that equal the discharging capacity of another in the lower part of the table, follow down the column the size of the smaller pipe until it intersects the line of the larger one. Thus, to find the number of 2-in pipes that equal in discharging capacity a 10-in pipe, follow down the column marked 2 to where it intersects the line marked 10 and it will be found that 80.4 2-in pipes are equal to one 10-in pipe.

In like manner the size of main required to serve several branches of different sizes can be determined. Suppose it is necessary to find the diameter of main that will serve one 2-in, one 3-in and one 4-in pipe. Use the capacity of the smallest pipe as a measure Then, one 2-in pipe has the capacity of one 2-inch pipe; one 3-in pipe has the capacity of 3.06 2-in pipes; one 4-in pipe has the capacity of 6.47 2-in pipes. The combined capacity of the pipes equals 10.53 2-in pipes. From the table it is found that a 5-in pipe has the capacity of 11.9 2-in pipes, so would be more than large enough to serve all the branches.

Hot-Water Supply. Gas, steam and coal are generally used for HEATING WATER. In the larger buildings steam is used. In medium-sized buildings coal heats the water. In residences gas is generally the fuel for water-heating; it is also being used to an increasing extent in hotels and office-buildings of medium size.

The consumption of hot water in large office-buildings is not so large as might be expected. In the Equitable Building of New York City, having a tenancy of 12 000 people, the average monthly consumption does not vary much from about 15 000 cu ft. That is at the low rate of 1.25 cu ft or 9.35 gal per person per month, a little over 1 qt per day. The water is heated, however, to a temperature of 120° F. Water of 100° is as hot as can comfortably be used, so to cool 9.35 gal of 120° water to about 100° would require the admixture of 6½ gal of 60° water. That would give each tenant almost 16 gal of hot water for a working month of about 24 days. To heat this water requires 480 000 lb of steam, or 1 lb of steam for every 2 lb of water heated.

In the following tables are given, respectively, the hot water consumed daily for one week and the gas required to heat the water in a hotel-building and in several apartments. The data are obtained from meter readings by the American Gas Association.

Boiling-Point of Water. The TEMPERATURE at which water boils varies with the PRESSURE. In a vacuum of one pound absolute pressure water boils

Table XXXIV. Water-Heating Data for Office-Buildings

System	Fixtures	Monday to Friday, inclusive	Ordinary day	Entire week
31-section boiler; Thermo control; 1 000-gal storage; instantaneous hot-water service boiler	250 hot-water fixtures	Hot water used, gal	6 395	35 200
		Gas consumed, cu ft	11 311	69 200
		Temperature rise, deg. F.	65.6	65.8
		Temperature of water delivered	135.9	136.8
		Cu ft gas per gal	1.76	1.96

Table XXXV. Water-Heating Data—Apartments

Apartment No. 1

Temperature of water, deg. F	132	131	131
Cu ft gas per gal	1.56	1.63	1.62

at a temperature of 102.018° F. At 15.31 lb gauge pressure, water boils at 250.293° F. The relation between the boiling temperature of water and the pressure is absolute; pressure cannot be increased without increasing the temperature, nor can the temperature of the boiling-point of water be increased without increasing the pressure.

The temperatures and corresponding pressures of boiling water can be found in Table XXXVI.

Expansion of Water. When water at or above the temperature of 39.1° F. is heated it increases in VOLUME. The temperature 39.1° F. is known as the POINT OF MAXIMUM DENSITY. When the water is at a lower temperature the application of heat causes it to contract and decrease in bulk, and the withdrawal of heat causes it to expand and increase in volume.

Table XXXVI. Boiling-Point of Water

The expansion, weight, density and comparative volume of pure water at different temperatures can be found in Table XXXVII.

Transmission of Heat to Water. Heat must be transmitted from the heating-medium to water through the walls of a COIL OR CONTAINER. The RATE at which heat can be transmitted depends upon the material through which the heat must pass. Copper, brass, wrought iron or steel and cast iron are the only materials used to any extent in the manufacture of heaters for water. The RATE OF HEAT-TRANSMISSION for these materials can be found in Table XXXVIII. The table is based on the assumption that the transmitting surface is clean and free from ash or incrustation of any kind.

The QUANTITY of heat transmitted depends upon the difference in tem-

perature between the heating-medium and the absorbing water, the thickness of the walls of the vessel and the material of which it is made.

Table XXXVIII. Comparison of Heat-Transmitting Surfaces

Material	Heat transmitted per square foot of heating surface per hour for each degree F. difference between the heating medium and the water
Copper plate.... . . .	275 Btu
Copper or brass pipe..	300 Btu
Wrought-iron or steel pipes	200 Btu
Cast-iron surface..	80 Btu

Capacity of Coal-Burning Water-Heaters. The capacity of a water-heater depends upon the amount of coal it can burn efficiently during a given period of time, the thickness and conductivity of the walls of the fire-box. Boiler iron is a better conductor of heat than cast iron; therefore a heater made of boiler iron of given surface will heat more water in an hour than will a cast-iron heater of equal surface, the amount of coal burned and the intensity of the fire being equal in both cases.

The amount of coal economically burned in a heater depends upon the area of grate and the size of the smoke-flue. Heaters burn from 3 to 6 lb, and will probably average 4 lb of coal per hr per sq ft of grate-surface. The total heat of combustion of a pound of anthracite coal of average composition is 14 133 Btu. Of this amount, however, a large percentage passes up the chimney as hot gases, and is otherwise lost, so that under ordinary conditions only about 8 000 Btu are actually available for transmission to the water.

Commercially, water-heaters are rated on a certain firing. That is, it is assumed that the heater will be charged with coal once in a given number of hours. Eight hours is assumed as the IDEAL FIRING-PERIOD. This means that the boiler will need attention only three times in 24 hr. The combustion-chamber is made large enough to hold the necessary coal for the 8-hr firing-period, and the grate-surface large enough to burn the coal. The heater then possesses a large reserve capacity. By cutting down the firing-period to 4 hr, the amount of water that can be heated will be almost doubled.

For this reason, the rating of a water-heater means little or nothing unless the firing-period is stated. One boiler might be heating a given quantity of water on an 8-hr firing. A smaller heater would heat the same quantity of water through the same range of temperature operating on a 4-hr firing-period. Both heaters could claim the same rating if the firing-period were not considered, although one of the heaters would have only about 50% the capacity of the other.

The HEAT-TRANSMISSION to water through coils or other heating surface is based on the assumption that the surfaces on both sides of the transmitting material are CLEAN and free from INCRUSTATION OF LIME OR MAGNESIA. However, no surface is free from incrustation after having been in service for some time. All water, even the softest, generally contains a small proportion of lime or magnesia, and it may be assumed that the softest of water is at least one degree hard. The lime or magnesia causing hardness of water, deposits on the water-heating coils, building up from year to year in proportion to the

hardness of the water. This scale will cut down the heat-transmission of the coils as follows:

$\frac{1}{16}$-in lime scale will cut down the heat transmission 13%
$\frac{1}{8}$-in lime scale will cut down the heat transmission 22%
$\frac{1}{4}$-in lime scale will cut down the heat transmission 38%
$\frac{3}{8}$-in lime scale will cut down the heat transmission 50%
$\frac{1}{2}$-in lime scale will cut down the heat transmission 60%
$\frac{3}{4}$-in lime scale will cut down the heat transmission 90%

In view of the progressive loss of heat-transmissions of coils and heaters, allowance must be made of sufficient excess capacity when new to offset the loss of capacity when old, and provision made to clean or replace the coils before the loss becomes excessive.

Temperature of Water Required. The TEMPERATURE OF WATER required for various classes of service may be found in Table XXXIX.

Table XXXIX. Temperatures of Water for Various Services

Class of service	Temperature required, deg. F.	
	Minimum	Maximum
Garages (for washing cars)	80	100
General domestic use	130	160
Laundry (hand work)	115	212
Laundry (machine work)	180	212
Barber shop (non-sterilizing)	115	150
Bar and soda fountains (hot drinks)	175	212
Lavatory and cleaning uses	115	150
Baths only	110	150
Shower-baths	110	150
Swimming-pools	80	212
Baptistries	80	212
Dishwashing (hand work)	130	212
Dishwashing (machine)	180	212
Milk dealers (not sterilizing or pasteurizing)	115	150

Heating Water with Steam. Water for use in large quantities is generally heated by means of steam by the aid of STEAM-COILS. Generally speaking, coils of brass or copper are preferable to iron for this purpose, although there are uses for which copper or brass pipe could not be employed. The rate of transmission of heat is 50% greater through brass or copper coils than through equal sizes of iron or steel coils.

The SIZE OF STEAM-COIL in square feet required to heat a certain quantity of water in a given time can be found by the following rule:

Rule. Multiply the weight of water in pounds by the number of degrees temperature F. the water is to be raised, and divide the product by (300, if the coil is brass or copper; 200, if the coil is iron or steel) times the difference between the temperature of the steam and the average temperature of the water.

In computing the HEATING-SURFACE of coils the INNER SURFACE of the pipe is taken, as that is the real heating-surface to which heat is applied. The

average temperature of the water in contact with the coil is taken as the temperature of the water.

Example. How many square feet of heating surface will be required in a copper coil to heat 300 gal of water per hour from 50° to 200° F. with steam 15-lb gauge pressure?

Solution. $300 \times 8.3 = 2\,490$ lb of water to be heated $200° - 50° = 150°$ rise in temperature of water. $(150° \div 2) + 50 = 125°$ = average temperature of water. $250°$ = temperature of steam at 15-lb gauge pressure. $250 - 125 = 125$ = the difference between temperature of steam and average temperature of water. Then:

$$\frac{2\,490 \times 150}{300 \times (250 - 125)} = 9.9 \text{ sq ft of copper coil}$$

The following constants will be found convenient in proportioning steam-coils for heating water:

W = gallons of water to be heated.
$W \div 10$ = sq ft of iron pipe-coil required for exhaust-steam.
$W + 15$ = sq ft of copper pipe-coil required for exhaust-steam.
$W \times 0.07$ = sq ft of iron pipe-coil for 5 lb pressure-steam.
$W \times 0.045$ = sq ft of copper pipe-coal for 5 lb pressure-steam.
$W \times 0.05$ = sq ft of iron pipe-coil for 25 lb steam-pressure.
$W \times 0.035$ = sq ft of copper pipe-coil for 25 lb steam-pressure.
$W \times 0.04$ = sq ft of iron pipe-coil for 50 lb steam-pressure.
$W \times 0.25$ = sq ft of copper pipe-coil required for 50 lb steam-pressure.
$W \times 0.03$ = sq ft of iron pipe-coil required for 75 lb steam-pressure.
$W \times 0.02$ = sq ft of copper pipe-coil required for 75 lb steam-pressure.

Drinking-Water Supply for Buildings. Drinking-water, filtered and cooled, has become an almost indispensable item of equipment for large buildings. Such a system is shown diagrammatically in Fig. 11. It consists of a grid of riser-branches indicated by solid lines, and returns or circulation-pipes indicated by dotted lines.

Pumps are necessary to keep the water in circulation, and the drinking-fountain branches are taken off the vertical risers so that the water delivered at the faucets will be direct from the cooling-coils. The system consists essentially of a set of water-filters, a cooling-tank, circulating-pumps and a balancing-tank. Water is drawn by the pumps through the filters and cooling-tank and is forced upward to the balancing-tank (Fig. 12), from which it overflows back to the cooling-tank to be recooled and recirculated. Make-up water flows from the house-tank to the balancing-tank, where it is controlled by a ball-cock which keeps the system full of water at all times.

This method of make-up necessitates the use of tank-water which might or might not be filtered. An alternate method, therefore, is to discharge from the filter into a second balancing-tank located near the cooling-tank. The supply to this balancing-tank is controlled by a ball-cock, so that as water is drawn at a drinking-fountain the balancing-tank is automatically supplied with filtered water. The overflow from the upper balancing-tank flows back into this make-up balancing-tank. The upper balancing-tank is located at a level of 8 ft or more above the level of the highest fixture to be supplied with drinking-water.

In the diagram is shown a cooling-tank. This tank is provided with brine coils for cooling the water. The brine for the coils can be supplied from a general brine circulating system, or a special refrigerating unit provided for the purpose. In practice cross-connections and by-passes would be provided.

For instance, there would be two filters with a by-pass, and the filters would be cross-connected so that either, both, or none could be in service at one time. In like manner the lower balancing-tank could be by-passed.

In proportioning a drinking-water system, a per capita allowance of 1/4 to 1/8 gal capacity in the water-cooling tank will be found satisfactory for most installations.

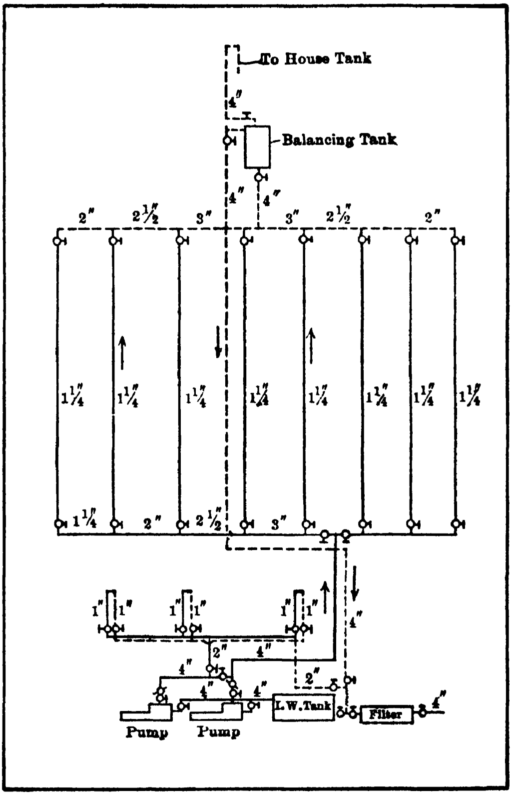

Fig. 11. Drinking-Water Supply for Buildings

It is necessary to INSULATE thoroughly all supply and return drinking-water pipes, otherwise they will condense the moisture in the atmosphere, thereby SWEATING and wetting ceilings over which they pass. It is equally necessary to cover the drinking-water pipes to prevent the water absorbing heat. Wastes from drinking-fountains ought likewise to be covered with anti-sweat covering.

Swimming-Pools are installed in club buildings, natatoriums, gymnasiums, and like buildings. They are approximately 25 by 75 ft in plan, or large enough for playing water-polo and similar games.

The pools are built with SLOPING BOTTOMS so that one portion of the tank has a depth of water from 4 to 5 ft and the deeper portion a depth of from 7 to 8 ft.

Provision is made to HEAT and STERILIZE the water in the pool. This is done by means of circulating-pumps which draw water from outlets at the bottom of the pool, pass it through a large strainer, a heater, filter, and steri-

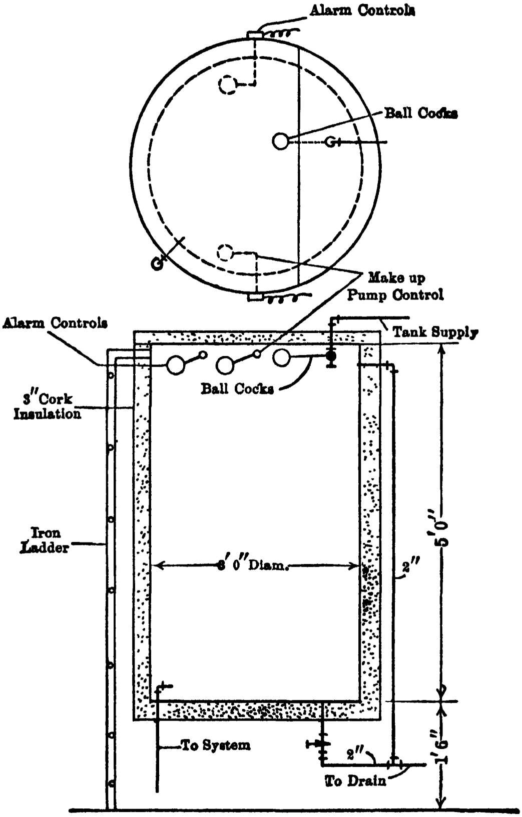

Fig. 12. Drinking-Water Balance Tank

lizer, and then back to the pool. The water returned to the pool flows in through a number of inlets spaced equally about the tank. An instantaneous steam water-heater is the type most favored for heating the water where a supply of steam is available throughout the year. A pressure type of SAND-FILTER is provided to remove all suspended matter in the water, and the sterilizing apparatus is used to rid the water of most of the bacteria. The two

types of sterilizing apparatus most in favor for sterilizing purposes are the ULTRA-VIOLET-RAY APPARATUS and CHLORINATING APPARATUS. The water in a swimming-pool ought to contain not more than 1 000 colonies of bacteria per cc on agar, incubated at 37.5° C., and a *B. coli* count of 1 per cc. The water should be taken from any part of the pool and examined within 48 hours.

In pools that are not treated with the chlorination process or ultra-violet rays, as many as 216 000 colonies of bacteria per cc have been found, and all samples showed gas indicating *B. coli*. A cubic centimeter is equal to about 15 drops.

When pools are so located that they cannot be emptied by GRAVITY, PUMPS must be provided with sufficient capacity to empty the pool in the shortest time allowable. Where revenue from the pool must be considered, the pumps ought to be able to empty the pool in 4 hr or less. Whatever repairs needed then can be made and the pool refilled without being out of service more than 8 or 10 hr.

For cleaning the walls and bottom of the pool without emptying the tank, a pool suction-pump, hose, and suction-nozzles similar to those used for vacuum-cleaning can be provided.

The large strainers on the recirculating line are better provided in duplicate, so that one can be cleaned while the other is in service.

Value of Pipe-Covering. There are many different uses for pipe-covering in plumbing practice. Cork covering or asbestos-sponge felted covering is used for drinking-water pipes; for hot-water pipes, 85% magnesia or air-cell asbestos is used, according to conditions. Anti-sweat covering should be used for wastes from drinking-fountains, cold-water pipes over ceilings, rain-leaders over finished ceilings, or other pipes that might condense moisture and allow it to drip where it would cause damage. Finally there is the frost-proofing of water-pipes exposed in cold places where they are liable to freeze.

Insulation for Hot-Water Pipes. Hot-water pipes and hot-water tanks when uncovered lose by radiation from their surface. To prevent this loss of heat and consequent extra consumption of coal, hot-water pipes, circulation-pipes and hot-water tanks in large institutions are generally covered with some non-heat-conducting material. The value of pipe-covering is not proportional to its thickness. Sectional pipe-coverings average about $1\frac{3}{8}$ in in thickness and reduce the loss by radiation about 90%. Doubling the thickness of pipe-covering saves only about another 5% of heat-loss. In specifying covering for pipes and boilers, therefore, a thickness of $1\frac{3}{8}$ in will be sufficient. Carbonate of magnesia is a very poor conductor of heat. Therefore, it is a good material for covering hot-water pipes. Carbonate of lime, on the other hand, is not a good covering material, although it often masquerades as carbonate of magnesia. When magnesia pipe-covering is specified, therefore, it is well to require a composition containing from 80 to 90% of magnesia, and require a test to be made at the expense of the contractor, but by a chemist named by the architect.

Expansion of Hot-Water Pipes. In all tall buildings expansion-loops ought to be placed in both the hot-water and the circulation-pipes, to permit the expansion and contraction of the lines without injury to the system. These loops are usually from 6 to 8 ft long, made up with elbows, and extend into the floor of the building. Generally the hot-water and circulation-pipes are supported midway between loops so that they can expand both up and down. The length that water-pipes will expand depends upon the degree to which they are heated, and the materials of which the pipes are made. The first of the

following four tables gives the expansion of cast-iron pipes, the second the expansion of wrought-iron pipes, the third the expansion of steel pipes, and the fourth the expansion of brass pipes.

Expansion of Cast-Iron Pipe

Temperature of air when pipe is fitted, deg. F.	Length of pipe when fitted, ft	Length of pipe when heated to							
		215° F.		265° F.		297° F.		338° F.	
		ft	in	ft	in	ft	in	ft	in
0	100	100	1 59	100	1.96	100	2.20	100	2.50

Liquid-Soap Systems. In large buildings, soap is conveyed to the various lavatories on the many floors as a liquid, through a system of piping.

Fig. 13 shows diagrammatically the way the system is installed.

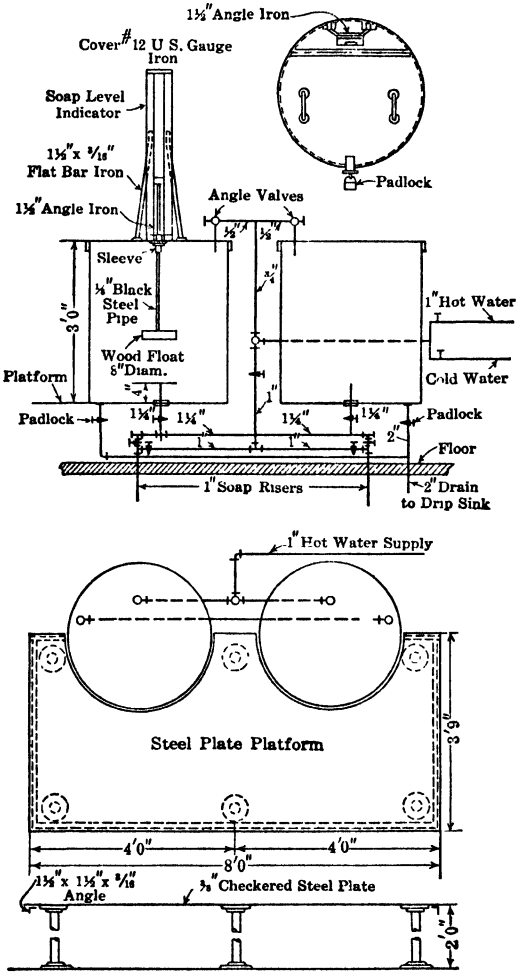

Fig. 13. Liquid Soap Tank

A battery of two SOAP-TANKS is provided, each tank having a capacity for a few weeks' supply of soap. Each tank is provided with hot and cold water for cleaning the tanks and also for mixing and thinning the soap solution

when necessary. Branches from the hot and cold-water pipes are connected to the soap-main, so that the main soap-pipe and its various branches can be flushed out whenever necessary. As there is a possibility of the soap sludging in the pipes, thereby stopping the flow if the liquid is not of the proper consistency, the FLUSHING CONNECTIONS are quite necessary. An iron platform with steps leading thereto is provided for convenience of the maintenance crew in charging the tanks

Black iron pipe is used for the soap-distributing system, and recessed drainage fittings are best for the mains and all branches 1 in in diameter and larger. They are equally desirable for the smaller sizes of pipe, but are not made in sizes smaller than 1 in.

At each battery of fixtures supplied with liquid soap, it is well to provide a PLUGGED CLEAN-OUT in the line (Fig. 14), so that in case the small pipe becomes clogged with soap it can be rodded out and flushed through the supply faucets.

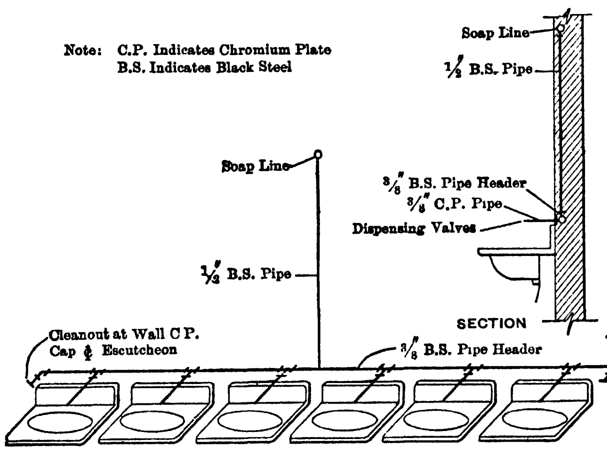

Fig. 14. Typical Soap Dispensing System

A $\frac{3}{8}$-in pipe is of sufficient size to supply a battery of fixtures. Generally the branch from battery supply to individual fixtures is $\frac{1}{4}$ in in diameter. As the consumption of liquid soap is small, the volume to be delivered can be taken care of by relatively small pipes. Where a battery of two tanks is installed, a header of $1\frac{1}{4}$-in pipe between the two tanks with a main drop riser of 1 in will be found of sufficient size. A 1-in drop riser will take care of 75 fixtures where the building is tall. In low buildings covering a large area it might be necessary to increase the soap-main one size.

Mixing and storage space in the liquid-soap tank of from 2 to 3 qt per fixture will be found a good proportion. A battery of two tanks is always convenient from an operating standpoint, as this enables a reserve tank of soap to be held ready for use at a moment's notice. A SOAP-LEVEL INDICATOR is provided at the tank so that the amount of unused soap in the tank can be seen at a glance.

It is good practice to continue the lower end of a drop riser, or the extreme

end of a long horizontal run, to a nearby slop-sink and control it there with a plugged valve. This will enable the operating force to flush out the pipes whenever necessary or desirable.

Testing Plumbing Systems

Testing Water-Supply Pipes. The water-distribution system of small buildings is generally tested by turning on the city water after plugging all the outlets. In tall buildings where the work is concealed and built in before the house-tank is ready to be filled, the system is tested by pumping it full of water and keeping it under pressure for 24 hours. Even when a tank supply is available it is well to test all lines to about 200-lb pressure per sq in.

Testing Drainage System. The drainage system is tested by plugging all outlets and filling the pipes with water. In tall buildings the work has to be tested in sections to keep up with the progress of the other trades. Special test fittings are provided for this purpose in the stacks at various floors, as for instance, the 12th and 24th floors of a 30-story building. The top section is tested first, the intermediate next, and the lowest section last. When applying a test to the lower section the water is allowed to rise to above the level of the test fittings so that all joints will have been under water.

The Smoke Test. A smoke test sometimes is applied as a final test. It consists, briefly, in pumping the system full of a dense pungent smoke under a slight pressure by means of a smoke-machine. The pressure should be only sufficient to balance a column of water one inch high. This is sufficient pressure to disclose any leaks, but is not great enough to force the seal in traps. The smoke test is of considerable value in disclosing leaks in small buildings, but of proportionally less value as the size of the building and drainage system increase. However, the smoke test is the best available for a final test and will have to continue in use until something better is evolved.

3. Illuminating-Gas and Gas-Piping

Varieties of Gas. There are five different kinds of gas used for domestic purposes. They are coal-gas, oil-gas, water-gas, natural gas, and acetylene-gas.

Coal-Gas is produced by the distillation or driving off of the light hydrocarbons, or gas, from bituminous coal. Nothing is added to the gas, and the by-products of distillation are coke, tar, and ammonia. Very little coal-gas is now used commercially.

Oil-Gas is made in much the same manner as coal-gas, by the process known as destructive distillation. This consists of heating the oil to a very high temperature, thereby causing the heavy hydrocarbons to break up into lighter or gaseous form. Animal and vegetable fats and oils, waste fats that occur in the manufacture of woolens, and ordinary rosins are used, as well as petroleum, in the manufacture of oil-gas.

Water-Gas, which is probably more extensively manufactured than any other kind of gas for general distribution, is made commercially by the contact of steam with incandescent carbon in the form of anthracite coal or coke. The steam is decomposed, the hydrogen being separated from the oxygen. The oxygen then takes up carbon from the coal or coke. This gas would burn with a non-luminous flame and would be useless for lighting except with incandescent mantles, so in practice the water-gas is enriched with oil-gas which

furnishes the hydrocarbon necessary to make a luminous flame, but this adds very little to the heating quality of the gas.

Natural Gas is obtained from drilled wells. In localities where it can be obtained it furnishes cheap light and fuel. The natural gas obtained in the hard-coal regions develops more heat per cubic foot in burning than any other kind of gas except acetylene. Natural gas is usually delivered under greater pressure in the street-mains and house-pipes than manufactured gas.

Acetylene-Gas is formed by bringing water and calcium carbide in contact. Calcium carbide is produced by the electrical fusion of coke and lime. It is a very hard substance like dark granite, has a very slight odor, will not burn or explode, and can be handled in any quantity with perfect safety. The fact that carbide begins to disintegrate and give off acetylene at the slightest touch of moisture makes it practicable to generate the gas in small quantities.

Process of Generating Acetylene-Gas. The satisfactory production of acetylene-gas requires a generator which shall feed carbide of sufficient size and weight to be plunged a sufficient depth under the water in the generator-chamber to insure coolness and proper washing. The carbide-chamber must be so arranged and protected that no gas can return to it to be wasted when the chamber is refilled. It must feed carbide loosely and in very small quantities to provide for perfect coolness by free access of water to all of the carbide. It must work automatically and with absolute certainty. Acetylene-gas to be pure must be thoroughly washed. Impure acetylene, as with any other illuminating-gas, means a discoloration of the flame, diminished illuminating power, clogging of pipes and burners with carbon and other foreign matter, and smoky burners, causing blackening of ceilings and tarnished and soiléd woodwork and upholstery. It is now generally agreed that the requirements above outlined can be attained only by a generator of the plunger-type. Portable generators are made in sizes of 5, 10, 15, 20 and up to 500-lights capacity. In all machines dropping carbide into water there should be a connection open from the carbide-holding receptacle to the safety-vent run out of doors from the gasometer. To develop the full illuminating power of the gas it is necessary to use a burner-tip having the thinnest slit obtainable, the illuminating power of the gas being about fifteen times that of coal-gas, for the same consumption. The light is a clear white, very nearly resembling sunlight in color and diffusiveness, with none of the red of the incandescent lamp, the orange of the ordinary gas-flame, or the green tone of the incandescent mantle; and it possesses the quality, unique among artificial illuminants, of reproducing even the most delicate shades of color as faithfully as sunlight. Even when used with mantle-burners, as it may be with great economy, acetylene-light presents a strong dissimilarity from ordinary gas under the same conditions. Acetylene corrodes silver and copper, but does not affect brass, iron, lead, tin, or zinc.

Piping a House for Gas

General Principles and Requirements. Ordinary wrought-iron or steel pipe is used in piping for all kinds of gas. Galvanized malleable-iron fittings are generally used in preference to plain iron fittings. Leaks should never be made tight with gas-fitters' cement. It cracks off easily and will melt in warm places. When pipes under floors run across floor-joists, the joists should be notched near their ends, or where supported by partitions, and not near the middle of the spans. It is evident that a 10-in joist, notched 2 in in the middle of the span, is no stronger than an 8-in joist. The whole system

of piping must be free from low places or traps and should pitch toward the main rising pipe. The riser should run up in a partition as near the center of the building as is practicable. It is obvious that where gas is distributed from the center of a building, smaller running lines of pipe will be needed than when the main pipe runs up on one end. Hence joists will not require as deep cutting, and the flow of gas will be more regular and even. For the same reason, in large buildings more than one riser may be advisable. Drip-pipes in a building should always be avoided. The whole system of piping should be so arranged that any condensed gas will flow back through the system and into the service-pipe in the ground. All outlet-pipes should be so securely and rigidly fastened in position that there will be no possibility of their moving when the fixtures are attached. Center pipes should rest on a solid support fastened to the floor-joists near their tops. The pipe should be securely fastened to the support to prevent lateral movement. The drop-pipe must be perfectly plumb, and pass through a guide fastened near the bottom of the joists, which will keep it in position and not be easily displaced by lathers, masons, or other workmen. In the absence of express directions to the contrary, outlets for brackets should generally be 5 ft 6 in high from the floor, except that it is usual to put them 6 ft high in halls and bath-rooms. The upright pipes should be plumb, so that the nipples that project through the walls will be level. The nipples should project not more than ¾ in from the face of the plastering. Laths and plaster together are usually ¾ in thick; hence the nipples should project 1½ in from the face of the studding. Drop center pipes should project 1½ in below the furring, or joists if there is no furring, where it is known that there will be no stucco or centerpieces used. Where centerpieces are to be used, or where there is a doubt whether they will be or not, then the drop-pipes should extend about a foot below the furring. All pipes being properly fastened, the drop-pipe can be safely taken out and cut to the right length when fixtures are put on. Gas-pipes should never be placed on the bottoms of floor-joists that are to be lathed and plastered, because they are inaccessible in the contingency of leakage, or when alterations are desired. The whole system of piping should be tested under a pressure of air that will raise a column of mercury 6 in high in a glass tube. The pipes are either tight or they leak. There is no middle ground. If they are tight the mercury will not fall a particle. A piece of paper should be pasted on the glass tube, even with the mercury, to mark its height while the pressure is on. The system of piping should remain under test for at least a half-hour.

Rules and Table for Proportioning Sizes of House-Pipes for Gas *

Rules Governing Sizes of Gas-Pipes. Table XL is based on the well-known formula for the flow of gas through pipes. The friction, and therefore the pressure necessary to overcome the friction, increases with the quantity of gas that goes through, and as the aim of the table is to have the loss in pressure not exceed 1/10 in water-pressure in 30 ft, the size of the piping increases in going from an extremity toward the meter, as each section has an increasing number of outlets to supply. The quantity of gas the piping may be called on to pass through is stated in terms of ⅜-in outlets, instead of cubic feet, outlets being used as a unit instead of burners, because at the time of first inspection the number of burners may not be definitely determined. In making the table, each ⅜-in outlet was assumed to require a supply of 10 cu ft per hour. In using the table observe the following rules:

* The Denver Gas and Electric Company.

(1) No house-riser shall be less than ¾ in. The house-riser is considered as extending from the cellar to the ceiling of the first story. Above the ceiling the pipe must be extended of the same size as the riser, until the first branch line is taken off.

(2) No house-pipe shall be less than ⅜ in. An extension to existing piping may be made of ¼-in pipe to supply not more than one outlet, provided said pipe is not over 6 ft long.

(3) No gas-range shall be connected with a smaller pipe than ¾ in.

(4) In figuring out the size of pipe, always start at the extremities of the system, and work TOWARD the meter.

(5) In using the table, the lengths of pipe to be used in each case are the lengths measured from one branch or point of juncture to another, disregarding elbows or turns. Such lengths will be hereafter spoken of as SECTIONS. No change in size of pipe may be made except at branches or outlets, each section therefore being made of but one size of pipe.

(6) If any outlet is larger than ⅜ in it must be counted as more than one, in accordance with the schedule below:

Size of outlet, inches........	½	¾	1	1¼	1½	2	2½	3	4
Value in table................	2	4	7	11	16	28	44	64	112

(7) If the exact number of outlets given cannot be found in the table, take the next larger number.

(8) If, for the number of outlets given, the exact length of the section which feeds these outlets cannot be found in the table, the next larger length, corresponding to the outlets given, must be taken to determine the size of pipe required. Thus, if there are eight outlets to be fed through 55 ft of pipe, the length next larger than 55 in the eight-outlet line in the table is 100, and as this is in the 1¼-in column, that size pipe would be required.

(9) For any given number of outlets, do not use a smaller size pipe than the smallest size that contains a figure in the table for that number of outlets. Thus, to feed 15 outlets, no smaller size pipe than 1 in may be used, no matter how short the section may be.

(10) In any piping-plan, in any continuous run from an extremity to the meter, there may not be used a longer length of any size pipe than found in the table for that size, as 50 ft for ¾ in, 70 ft for 1 in, etc. If any one section would exceed the limit length, it must be made of larger pipe. Thus, 6 outlets could not be fed through 75 ft of 1-in pipe, but 1¼ in would have to be used. When two or more successive sections work out to the same size of pipe and their total length or sum exceeds the longest length in the table for that size pipe, make the section nearest the meter of the next larger size. For example, if we have 5 outlets to be supplied through 45 ft of pipe and these 5 and 5 more, making 10 in all, through 30 ft of pipe, we should find by the table that 10 outlets through 30 ft would require 1-in pipe, and that 5 outlets through 45 ft would also require 1-in pipe, but as the sum of the two sections, 30 plus 45 equals 75 ft, is longer than the amount of 1 in that may be used in any continuous run, the 30-ft section, being the one nearer the meter, must be made of 1¼-in pipe. The application of the limit in length of any one size in a continuous run may also be shown as follows· Eight outlets will allow of 13 ft of ¾-in pipe in the section between the eighth and ninth outlets (counting from the extremity of the system toward the meter), provided that this 13 ft added to the total length of ¾-in pipe that may have been used between the extremity of the run and the eighth outlet does not exceed 50 ft, which, according to the table, is the greatest length of ¾ in allowable in any one branch of the system. Therefore, up to the eighth outlet, 37 ft of ¾-in pipe could have

Table XL. Showing the Correct Sizes of House-Pipes for Different Lengths of Pipes and Number of Outlets

Number of ⅜-in outlets	Lengths of pipes in feet									
	⅜-in pipe	½-in pipe	¾-in pipe	1-in pipe	1¼-in pipe	1½-in pipe	2-in pipe	2½-in pipe	3-in pipe	4-in pipe

50							45	135	330	600
65							27	80	200	600
75							20	60	150	600
100								33	80	360
125								22	50	230
150								15	35	160
175									28	120
200									21	90
250									14	59

been used, and yet allow 13 ft of ¾ in to be used in the section between the eighth and ninth outlets. If more than 37 ft had been used, then the entire 13 ft between the eighth and ninth outlets would have to be of 1-in pipe.

(11) Never supply gas from a smaller size of pipe to a larger one. If we have 25 outlets to be supplied through 200 ft of pipe, and these 25 and 5 more, making 30 in all, through 100 ft of pipe we should find by the table that 25 outlets through 200 ft would require 2½-in pipe, and 30 outlets through 100 ft would require 2-in piping, but as under this condition a 2-in pipe would be supplying a 2½-in pipe, the 100-ft section must be made 2½ in. The sizes of pipes in Fig. 15 are in accordance with the foregoing rules and the table.

Heat Units in Gas. There is no one definite number of heat units that can be given as the heat value of gas. As already pointed out, there are three processes of manufacture of artificial gas, all of which are used throughout the country. Of the manufactured gases, two or more kinds are sometimes combined, for instance, when oil-gas is added to water-gas. Then, too, natural gas is now being mixed with manufactured gas, so that the exact

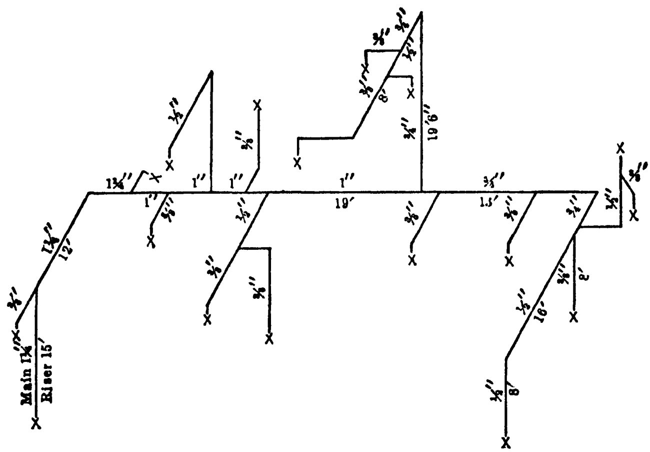

Fig. 15. Diagram of Gas-piping

amount of heat given off by a cubic foot of gas will depend upon the standard of the local gas company.

Manufactured gas is generally said to contain 700 heat units, and natural gas from 740 to 1 117, or an average of 950, heat units per cu ft, according to the territory where the natural gas is produced. As a matter of fact, the heat contained in manufactured gas varies from 500 to 600 Btu. It seldom exceeds 650. In some states the heat value of gas is governed by laws, and the tendency seems towards establishing a standard of 525 Btu per cu ft of manufactured gas.

CHAPTER XXXIII

ILLUMINATION OF BUILDINGS

By

W. H. TIMBIE

PROFESSOR OF ELECTRICAL ENGINEERING, MASSACHUSETTS INSTITUTE OF TECHNOLOGY

AND

P. H. MOON

ASSISTANT PROFESSOR, MASSACHUSETTS INSTITUTE OF TECHNOLOGY

General Aims. The illumination of buildings is assuming a position of ever-increasing importance. The old method of installing a few lights more or less at random has been superseded by the inclusion of lighting as an integral part of the building design. Only in this way is a thoroughly pleasing and adequate installation possible. There has also been a breaking away from the stereotyped forms of lighting fixtures and a great influx of new ideas leading to various types of luminaires and luminous panels. There is also an increase in the use of artificial skylights and of cove lighting. All these must be built in and cannot be added readily as an afterthought.

Interiors should be adequately illuminated to minimize eye-strain, reduce accidents, and give a pleasing and cheerful effect. Even more important is the requirement that there shall be freedom from glare, nothing being more fatiguing than facing a glaring light source, either directly or by reflection in a polished desk-top. The aim should be to produce a lighting installation which will give soft, well-diffused, glareless but adequate illumination.

Of the result, the eye is the final judge, and on its verdict the lighting system stands or fails. The esthetic elements are of prime importance in many cases; they are, of course, hardly amenable to calculation. There remain, however, a great many factors which can be calculated easily, and such calculations will often save costly mistakes. It is the purpose in the following pages to give general design principles for various types of installations and to provide tables showing modern practice.

Nature of Light. Electromagnetic waves are used almost continuously during the waking moments of every normal human being. Comparatively long waves are utilized in RADIO; the broadcast band, for instance, running from wave-lengths of 200 to 550 meters (about 650 to 1 800 ft). A band of shorter waves is known as the INFRA-RED, and is responsible for most of the heat we receive from the sun as well as for the energy radiated from all hot bodies here on earth. We use extremely short electromagnetic waves in the form of X-RAYS, while somewhat longer waves are known as ULTRA-VIOLET. But of greatest importance to the human race is a band having wave-lengths from about 0.00004 to 0.00007 cm. These are important, not because of any inherent characteristic of the waves themselves, but due to a peculiarity of the human eye which responds to electromagnetic radiation of only these lengths.

It has been found that the sun produces practically all wave-lengths, not only in the visible range but also in the near-by ultra-violet and infra-red. In the visible region, differences in length are perceived as different COLORS. The approximate wave-lengths corresponding to the colors are as follows:

Violet	0.000040 to 0.000045 cm
Blue	0.000045 to 0.000049 cm
Green	0.000049 to 0.000055 cm
Yellow	0.000055 to 0.000059 cm
Orange	0.000059 to 0.000063 cm
Red	0.000063 to 0.000070 cm

Light from the sun contains all these colors and gives the sensation of WHITE LIGHT. A light source which gives out a preponderance of long waves will be expected to have a REDDISH or ORANGE color. For instance, the well-known neon sign emits nearly all its energy at long wave-lengths and gives a characteristic red-orange light.

Some objects reflect light-waves of a certain length only, and absorb all the rest. It is this property that gives color to objects. Suppose, for instance, that a piece of cloth is receiving light from the sun, all of which is absorbed except the waves of proper length to cause a sensation of green. The green waves only would then come from the cloth to the eye, all the rest being absorbed, and the cloth would appear green. If it absorbed waves of all lengths, it would appear black, because no light would be reflected from it to the eye. If now the piece of cloth, which absorbs all wave-lengths except that of green, were exposed to a source of light which was emitting all colors EXCEPT GREEN, there being no green waves to be reflected from it, the cloth in this light would appear black. Suppose a piece of cloth absorbed all colors but two, say violet and red. When light having all wave-lengths fell upon it, it would absorb all the waves except violet and red. These two the cloth would reflect as a mixture and would appear purple. If, however, the source of light contained no violet waves, it could only reflect the red waves and appear red. This light, then, would not cause the cloth to show its normal color. So in choosing an artificial source of light, it is necessary to select one which will send out all wave-lengths, if we wish to have the different objects appear in their normal colors

Experiment has shown that though incandescent lamps emit all wave-lengths in the visible region, they do not give them in the correct proportions to produce white light. The old carbon lamp gave a light which was distinctly reddish in color. The modern tungsten lamp, particularly in the largest sizes, is much better in this respect, though the light is still far from white. Thus where it is necessary to match colors, special filters must be used in front of the lamps. These cut out some of the red rays and give a nearly white light at the expense of efficiency. Except for color matching, the color of the clear or frosted Mazda lamp is usually considered satisfactory.

Vision. As previously stated, the eye is only sensitive to a certain limited band of wave-lengths and is blind to electromagnetic waves of other lengths. It sees the waves of lengths from about 0.00004 to 0.00007 cm as different colors, ranging from a deep violet at the former to a deep red at the latter limit. But it does not see all colors equally well. It favors the yellow-green, and becomes less and less sensitive as the ends of the visible spectrum are approached. This is shown in Table I, which gives the internationally accepted values of relative visibility. These results are an average of tests made by a large number of observers.

Table I

	Wave-length	Relative visibility		Wave-length	Relative visibility
Violet . . .	0.000040 cm	0 0004	Yellow. .	0.000056 cm	0 995
	41	0 0012		57	0 952

	54	0 954		70	0.0041
	55	0.995			

Luminous Flux. Quantity of light is measured in LUMENS.* Exactly how the lumen is measured and how it is standardized need not concern us here. For this information the reader is referred to any text on illumination. Suffice it to say that the total amount of light emitted by light sources is measured in lumens, values being furnished by the lamp manufacturers. In the earlier days of the industry, incandescent lamps were rated in CANDLES but this has been superseded by the specification of lumens. Thus the luminous flux from an ordinary 100-watt frosted-globe tungsten lamp is 1 340 lumens. This can be redirected by various kinds of reflectors or luminaires, and finally it can be spread over a portion of a room to give a satisfactory illumination.

Illumination. By the ILLUMINATION of a surface we mean the amount of light falling upon a unit area of that surface. Illumination is usually expressed in LUMENS PER SQUARE FOOT or FOOT-CANDLES. The two terms are synonymous, but the former is the preferable one and will be used in this treatise.

For instance, a desk-lamp using a 25-watt bulb and directing 200 lumens of light onto a desk 3 ft $\times$ 4 ft will produce an average illumination of

$$\frac{200}{3 \times 4} = 16.7 \text{ lumens/ft}^2$$

Intensity of a Point Source. A point source of light is said to have an INTENSITY OF ONE CANDLE if it illuminates a sphere of one-foot radius to one lumen/ft^2 when the light is placed at the center of this sphere. For engineering purposes it is usually permissible to consider incandescent lamps and even luminaires as point sources.

Brightness. For light sources which are not point sources, the term BRIGHTNESS may be used. The brightness of a luminous surface is defined

* The internationally accepted definition of *light* or *luminous flux* is the rate of flow of radiant energy evaluated with respect to the visual sensation. It is measured in lumens.

as the intensity per unit of projected area, and is often expressed in CANDLES PER SQUARE FOOT.

Measurement of Illumination. The eye is notoriously poor as an instrument for the measurement of illumination. Like the ear, it is capable of detecting small DIFFERENCES but cannot give ABSOLUTE VALUES with any degree of accuracy. Thus to determine whether the illumination produced by an existing lighting installation is sufficient or satisfactory as regards uniformity, some form of measuring instrument is necessary. Two types are in use today—the FOOT-CANDLE METER and the MACBETH ILLUMINOMETER.

The FOOT-CANDLE METER is shown in Fig. 1. A series of translucent openings in the top panel is lighted from within by a small incandescent lamp

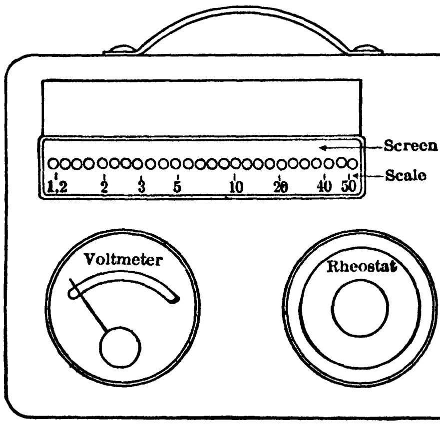

Fig. 1. Foot-candle Meter

which is so arranged that the openings constitute a series of spots varying from very low brightness on the left to great brightness on the right. The internal lamp is operated from a flash-light battery within the case, and the rheostat (lower right) is adjusted to give constant voltage across the lamp as indicated by the voltmeter (lower left). To determine the illumination at any point, on a desk, for instance, the meter is placed on the desk at that point, the rheostat is adjusted to give rated voltage, and the illumination is read off the scale of the instrument by selecting the particular spot which appears to be the same brightness as its background.

The MACBETH ILLUMINOMETER (Fig. 2) is a much more accurate and versatile instrument. Besides the instrument proper shown in Fig. 2, there is included a battery box with rheostats and ammeter for supplying the lamp, portable standard lamp, test-plate, filters, test-plate tripod, etc. The instrument is generally used with a special glass TEST-PLATE about 6 in in diameter, which is placed where the illumination is to be measured. The illuminometer is then sighted on the test-plate and the internal lamp is moved back and forth until the two comparison surfaces appear to be of the same brightness. The illumination (lumen/ft^2 or foot-candles) is then read directly on a scale attached to the movable lamp.

If the illumination is greater than 25 or less than 1 lumen/ft², filters can be used to extend the range. For daylight illumination a special filter is used to give a good color match in order to facilitate the measurements

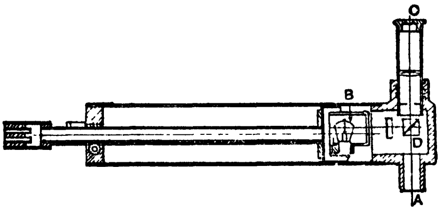

Fig. 2. Section of Macbeth Illuminometer *

Light Sources

The Sun. The sun is still used for interior illumination more than any artificial source. It has a diameter of 865 000 miles, is at a distance of approximately 93 000 000 miles, and has a brightness of the order of 200 000 candles per cm². This brightness is greatly in excess of anything obtainable on the earth. As noted from Table II, the crater of the carbon arc is only about 1/12 as bright. The light received from the sun contains all colors but is somewhat stronger in the center of the spectrum (yellow-green) than at the ends of the spectrum. It is an interesting fact that our eyes are also most sensitive to light of this color, which would seem to indicate that by a process of evolution the eye has fitted itself particularly to sunlight.

Incandescent Lamps. Since the first incandescent lamp of 1879 there has been continuous progress leading to greater efficiency and whiter light. (See Table III.) This has been brought about by improvements in the technique of manufacture and by the use of filament materials which can be operated at higher temperatures. As the temperature of the filament is raised the amount of light increases very rapidly and becomes more nearly white in color.

The light given off by a lamp is measured in LUMENS, while the electrical input is expressed in WATTS. Thus the efficiency is usually given in LUMENS PER WATT. Efficiency can also be expressed in per cent by using the experimentally determined relation that 670 lumens = 1 watt. For instance, the ordinary 100-watt lamp has an efficiency of 13.8 lumens/watt. In per cent this is $\frac{13.8}{670} = 2.0\%$ efficiency. Expressed in this way, the best of modern lamps show themselves to be distressingly inefficient. A large proportion of the energy given off by incandescent lamps is in the form of long infra-red rays which give no sensation of light but heat any objects on which they fall. That this heat must be taken into account in some cases is shown by the fact that in the ballroom of the St. George Hotel, Brooklyn, N. Y., 2 500 sq ft of direct heating surface were eliminated because of the large number of lamps used for lighting.

Mazda B and Mazda C Lamps. Two types of lamps are made today—the VACUUM LAMP (Mazda B) and the GAS-FILLED LAMP (Mazda C). The aim of the lamp manufacturers is to operate filaments at the highest temperature

consistent with a life of 1 000 hours. In a vacuum lamp this temperature is limited not by the melting-point of tungsten but by the large amount of tungsten which is evaporated from the filament at high temperatures. This evaporated tungsten deposits on the bulb in the form of a black powder which cuts down the life. Thus in a vaccum lamp it is necessary to operate the filament far below the melting-point to prevent blackening of the bulb.

Table II. Brightness of Some Light Sources

Source	Temperature, deg. *K*	Brightness, candles/cm²
Sun	....	200 000
Clear sky (average)	. .	0.4
Searchlight arc	... .	50 000
Crater of solid carbon arc	....	16 000
Mercury vapor lamp	. .	2.3
900-watt projection lamp	3 290	2 630
1 000-watt tungsten lamp	2 990	1 210
500-watt tungsten lamp	2 930	1 000
100-watt tungsten lamp	2 760	579
40-watt tungsten lamp	2 465	203
Metalized-carbon lamp (G. E. M.)	2 195	78.1
Treated-carbon lamp	2 165	70.6
Untreated—carbon lamp	2 080	54.9
Candle flame	. .	0.5
Welsbach gas-mantle	1 900	5

It has been found, however, that by filling the bulb with an inert gas the evaporation of the filament is greatly reduced, and thus it is possible to operate the filament at a higher temperature. At the present time all 115-volt lamps above 40 watts are gas-filled. With small lamps the loss in heat by convection currents in the gas more than balances the gain due to higher filament temperature, so that vacuum lamps are more efficient than gas-filled lamps in the small sizes.

Table III. Improvements in Incandescent Lamps

Date	Lamp	Approximate efficiency, lumens/watt
1879	Edison's first successful lamp (carbonized thread filament)	1.4
1881	First commercial lamps (carbonized bamboo)	1.6
1893	Carbonized cellulose filament	3.4
1905	Metallized carbon filament (G. E. M.)	4.2
1906	Tantalum filament	4.8
1907	Pressed tungsten filament	8
1911	Drawn tungsten filament (vacuum)	10
1913	Drawn tungsten filament (gas-filled lamp)	20

Effect of Line Voltage. It is of the utmost importance that the lamps be correctly chosen as to voltage. If the actual voltage is 115, lamps rated at 115 volts should be used. The use of 120-volt lamps will give illumina-

tion which is poor both in amount and color. It seems better to err by using lamps rated at too low a voltage rather than the reverse. While it is true that this will reduce the life of the lamps, the efficiency will be considerably increased, which may more than compensate economically for the increased cost of lamp renewals.

A rough rule applicable over a small change of voltage is as follows:

A 1% increase in voltage causes a 1.5% increase in watts, a 3.5% increase in lumens, a 1.8% increase in efficiency and a 13% decrease in life.

More accurate formulas are:

$$\frac{W_1}{W_2} = \left(\frac{V_1}{V_2}\right)^n$$

$$\frac{F_1}{F_2} = \left(\frac{V_1}{V_2}\right)^k$$

$$\frac{L_1}{L_2} = \left(\frac{V_2}{V_1}\right)^d$$

in which W_1 = watts input at voltage V_1;
W_2 = rated watts;
F_1 = lumens at voltage V_1;
F_2 = rated lumens;
L_1 = life at voltage V_1;
L_2 = rated life;
V_1 = voltage at which lamp is operated;
V_2 = rated voltage.

The constants n, k, and d are as follows:

Type of Lamp	n	k	d
Vacuum	1.54	3.38	13.1
Gas-filled	1.58	3.51	13.5

Example. A 300-watt 120-volt lamp is operated at 112 volts. What are the characteristics?

Reference to Table IV shows that the standard 300-watt lamp emits 5 400 lumens and has a life of 1 000 hours at rated voltage.

At 112 volts, the input will be

$$W_1 = 300\left(\frac{112}{120}\right)^{1.58} = 270 \text{ watts}$$

The luminous output will be

$$F_1 = 5\,400\left(\frac{112}{120}\right)^{3.51} = 4\,260 \text{ lumens}$$

The life will be

$$L_1 = 1\,000\left(\frac{112}{120}\right)^{13.5} = 2\,490 \text{ hours}$$

The efficiency will be

$$F_1/W_1 = 15.8 \text{ lumens/watt.}$$

Thus the life is more than doubled but the efficiency has been reduced from 18.0 to 15.8 lumens per watt.

Table IV. Data on Some Standard Mazda Lamps

(Data compiled from Manufacturers' Schedules, Large Mazda Lamps, National Lamp Works.)

* White bowl.

All the above lamps are for 110, 115, or 120 volts. Type "B" is vacuum type; type "C" is gas-filled. Sizes below 250 watts have medium screw base; lamps above 250 watts are usually fitted with mogul base.

Lamp Data. Table IV gives a list of the lamps most frequently used for interior illumination and for building floodlighting. The bulbs are designated by a letter and a number, the former referring to the shape of the globe and the latter to its diameter. P is pear-shaped, S is straight-side, T is tubular, G is spherical. The number gives the largest diameter of the bulb in eighths of an inch. Thus a T–8 lamp has a tubular bulb 8 eighths or one inch in diameter.

Mercury Vapor Lamps. Another type of lamp used in industrial lighting is the mercury vapor lamp manufactured by the General Electric Vapor

Lamp Co. Fig. 3 shows the general appearance of the unit. Its characteristics are as follows:

Watts	=	450
Lumens	=	5 625
Lumens per watt	=	12.5

The light is a blue-green color; and, because of the entire absence of red or orange, cannot be used where colors must be seen in their true values. However, it is finding wide use in certain industrial applications such as machine shops wood-working plants, textile mills, drafting offices, and newspaper composing rooms. It is particularly fitted for inspection of many products since the almost monochromatic nature of the light promotes high visual acuity.

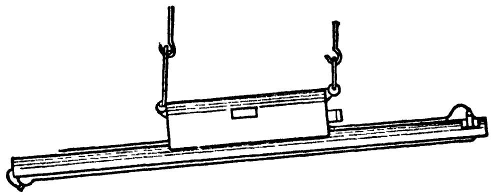

Fig. 3. Mercury-vapor Lamp

Calculation of Illumination

The Ideal Case. Consider first the IDEAL CASE of a perfect luminaire which absorbs no light, perfectly reflecting walls and ceiling, and an absorbing floor. Then all the light emitted by the lamp will be absorbed ultimately by the floor, no matter in what direction it is emitted by the luminaire or how many times it is reflected by walls or ceiling. Thus if the total light emitted by the lamp is F lumens, all this light must be distributed over the floor and the AVERAGE ILLUMINATION is

$$E = \frac{F}{A} \text{ (lumens/ft}^2\text{)} \tag{1}$$

where A is the floor area in sq ft.

The Coefficient of Utilization. In the actual case, some light is always absorbed by the luminaire, and if part of the output of the luminaire is directed at the ceiling or walls, a portion will be absorbed by them. So the illumination on the working plane will be reduced below the value (1). It is usual to introduce the COEFFICIENT OF UTILIZATION (k_u) to take care of this absorption of light. Thus in the actual room,

$$E = k_u \frac{F}{A} \tag{2}$$

k_u is always less than unity and approaches *one* the more closely the room and luminaire approach the ideal. k_u is a sort of efficiency—it tells how well the installation utilizes the light produced by the lamps.

It is evident that anything which affects the light distribution of the luminaire or the amount of light absorbed by the walls and ceiling will affect the coefficient of utilization. Thus k_u is a function of (1) The luminaire; (2) shape of room; (3) reflection factor of walls; (4) reflection factor of ceiling. The results of a large number of illumination measurements made with various-shaped rooms and different reflection factors of walls and ceiling

resulted in a set of tables by which the coefficient of utilization can be found in any ordinary case.

Table V.* Room Index for Narrow and Average Rooms

		Feet						
For indirect lighting use ceiling height		9 and $9\frac{1}{2}$	10 to $11\frac{1}{2}$	12 to $13\frac{1}{2}$	14 to $16\frac{1}{2}$	17 to 20	21 to 24	25 to 30

* From Westinghouse Lamp Co. Bulletin E-108.

Room Index. The effect of the second factor—shape of room—is evaluated from Table V. This gives what is known as the ROOM INDEX, a factor which is made equal to 1 00 for a cubical room. For instance, a room 14 × 14 × 14 ft has a room index of 1.0. It will also be noted that a high, narrow room has a small index caused by the comparatively large amount of light absorbed by the walls, while a large room with low ceiling has a large index because of the slight effect of the walls.

For instance, a room 24 ft high and 12 × 25 ft has a room index of 0.6, while a room 15 ft high and 60 × 100 ft has a room index of 4.0.

Calculation. Knowing the room index, the type of luminaire to be used, and the kind of walls and ceiling, one can refer to Table VI and obtain the coefficient of utilization k_u. The illumination is then determined very easily by use of Equation (2). This gives the average illumination on the working plane on the assumption of new lamps, clean luminaires, and freshly finished ceiling. To allow for a certain amount of dust, blackening of lamp bulbs, etc., DEPRECIATION FACTORS are given in Table VI. The actual average illumination which would be obtained some time after installation would be

$$E = \frac{F}{A} k_u \cdot k_d \tag{3}$$

in which k_d is this depreciation factor.

The use of Table VI requires an approximate knowledge of the reflection factor of walls and ceiling. This can be obtained from Table VII.

Example. What is the average illumination on the desk level 30 in above the floor in an office 15 × 25 ft having a ceiling height of 12 ft? It is lighted by two 500-watt lamps in prismatic glass inclosing units (No. 8, Table VI) which are hung 9½ ft above the floor. The walls and ceiling are fairly light (50% reflection factor).

First obtain the room index from Table V. Looking in the column of 9 and 9½ ft mounting height, one finds a ROOM INDEX of 1.2.

Table VI is next used to determine the coefficient of utilization and the depreciation factor. The COEFFICIENT OF UTILIZATION corresponding to this room index and this kind of walls and ceiling is seen to be 0.40. This means that 40% of the light emitted by the lamp actually gets down on the working plane. The DEPRECIATION FACTOR under average conditions is 0.70. Reference to Table IV shows that the 500-watt clear lamp gives 9 850 lumens.

Thus the illumination on the working plane is

$$E = \frac{9\,850 \times 2}{15 \times 25} \times 0.40 \times 0.70$$

$$= 14.7 \text{ lumens/ft}^2$$

Design of a Lighting Installation. (1) The first step is to decide upon the ILLUMINATION desired. Representative values are given in Tables VIII and IX. It should be realized, of course, that the value to be used is a matter of judgment on the part of the lighting engineer. The table, however, represents good practice at the present day. These values are much higher than were used a few years ago, the general tendency being to use higher levels of illumination as such become economically feasible.

Table VI.* A Guide to the Selection of Reflecting

Lighting unit		Efficiency based upon: Illumination on horizontal	Efficiency based upon: Illumination on vertical	Appearance of lighted room	Direct glare	Reflected glare	Shadows	Maintenance
Direct Lighting—General Industrial Reflectors

* From Westinghouse Lamp Co. Bulletin E-108.

A point often overlooked in this connection is that even with the highest values now in use the illumination is much less than what we are accustomed to get out of doors in the shade during the day, and is even considerably less than we get indoors during the day. The former value is of the order of 1 000 lumens/ft², and the latter may be from about 20 to 100 lumens/ft² under ordinary conditions. Thus even in a good modern lighting installation the illumination is below what we are accustomed to in the daytime.

(2) The second step is to decide upon the TYPE OF LUMINAIRE. This is entirely a matter of judgment. Such factors as esthetics, convenience, freedom from glare, cost, ease of cleaning, etc., should enter. To aid in the selec-

tion of the best type for the purpose, the left side of Table VI may be found useful.

Three General Systems of Lighting. Three systems of lighting are available, each having its own types of luminaires.

(a) Direct Lighting. A system is designated as DIRECT when more than one-half the light reaches the area to be illuminated by coming directly from the light-source, without being reflected from the ceiling or walls. This includes all systems using lamps with clear, frosted, translucent, or opalescent globes, or reflectors, in which the light is reflected downward. It is the most efficient system, was the first to be used, and is still the most common. The color of the walls or ceiling has less effect in this system than in the others.

(b) Indirect Lighting. A system is designated INDIRECT when all the light is thrown first on the ceiling and walls, and reflected from these to the surface to be illuminated. Any system which conceals the source of light by opaque reflectors is thus INDIRECT. Light finish must always be used on the walls and ceiling with this system. Even then, the efficiency is usually lower than that of a direct system, but the total absence of glare and shadows and the even distribution of light make this a popular scheme in restaurants, show-rooms, etc., where decorative lighting is desired.

(c) Semi-indirect Lighting. This system throws most of the light to the walls and ceiling, but allows a small percentage to be diffused through the reflector straight to the area to be illuminated. This system is rapidly coming

Table X. Spacing of Outlets *

Ceiling height (or height in the clear)	Spacing between outlets		Spacing between outside outlets and wall		Approximate area per outlet (at usual spacings)
	Usual	Maximum (for units at ceiling)	Aisles or storage next to wall	Desks, work-benches, etc., against wall	
ft	ft	Not more than †		Not more than †	sq ft
8	7	7½		3	50–60
9	8	8		3	60–70
10	9	9		3½	70–85
11	10	10½		3½	85–100
12	10–12	12	Usually one-half actual spacing between units	3½–4	100–150
13	10–12	13		3½–4½	100–150
14	10–13	15		4–5	100–170
15	10–13	17		4–5	100–170
16	10–13	19		4–6	100–170
18	10–20	21		4–6	100–400
20	18–24	24		5–7	300–500
22	20–25	27		5–7	400–600
24	20–30	30		6–8	400–900
26	25–30	33		8–9	600–900
30 and up	25–30	40		8–10	600–900

* From Westinghouse Lamp Co. Bulletin E-108.

† Where it is definitely known that some form of indirect lighting will be used, the maximum spacing between outlets may be increased about 2 feet, and the distance from the outside outlets to the wall may be increased by 1 ft.

into favor because apparently we have become accustomed to looking for the source of light and miss it when it is concealed as in the indirect system. The totally indirect fixtures often show up rather unpleasantly as a dark spot against a light background. This is avoided in the semi-indirect system. The slightly higher efficiency of this system is another advantage over the indirect. Any given room may usually be lighted by any one of the three systems, although it is generally true that conditions are such as to make one of the three more desirable than either of the other two.

Table XI. Mounting Height of Lighting Units

Direct lighting units				Semi-indirect and indirect lighting	
Actual spacing between units	Distance of units from floor not less than	Desirable mounting height in industrial interiors	Desirable mounting height in commercial interiors	Actual spacing between units	Recommended suspension length (top of bowl to ceiling)
ft	ft			ft	ft
7	8	12 ft above floor if possible—to avoid glare, and still be within reach from step-ladder for cleaning		7	1–3
8	8½			8	1–3
9	9			9	1–3
10	10		The actual hanging height should be governed largely by general appearance, but particularly in offices and drafting-rooms, the minimum values shown in column 2 should not be violated.	10	1½–3
11	10½			11	2–3
12	11			12	2–3
14	12½			14	2½–4
16	14			16	3–4
18	15	Where units are to be mounted much more than 12 ft it is usually desirable to mount the units at ceiling or on roof-trusses.		18	3–4
20	16			20	4–5
22	18			22	4–5
24	20			24	4–6
26	21			26	4–6
28	22			28	5–7
30	24			30	5–7

(3) The LOCATION OF OUTLETS is the next step. Table X will be found useful here. The object is to put the lights close enough together so that the illumination is uniform. If the luminaires are too far apart the illumination directly beneath them may be good but the values between will be poor. A general rule is to use a spacing between outlets approximately equal to the height of unit above the floor. The spacing between an outlet and the wall is usually made about half the spacing between two outlets.

A very common mistake in direct lighting is to use a mounting height which is too low. The use of a high mounting height (even higher perhaps than the recommended values of Table XI) has the following advantages:

(a) Raising the luminaire causes little change in the average illumination but makes the lighting more uniform.

(b) A greater mounting height allows greater spacing between units which reduces the cost of wiring.

(c) The use of a smaller number of luminaires of large size allows the use of larger lamps which are more efficient.

For indirect or semi-indirect lighting, most of the light comes from the ceiling, and the mounting height of the units has very little effect on the uniformity of illumination.

(4) Knowing the size of room and the finish of walls and ceiling, we next obtain the room index (Table V) and the coefficient of utilization (Table VI). The TOTAL LUMINOUS OUTPUT of the lamps must then be

$$F = \frac{A \times E}{k_u \times k_d} \tag{4}$$

in which A = floor area;
E = average illumination desired (Table VIII);
k_u = coefficient of utilization (Table VI),
k_d = depreciation factor (Table VI).

(5) The luminous output of each lamp is found by dividing F by the number of lamps. The nearest LAMP SIZE is then selected from Table IV. This completes the design of the lighting system for the room.

The Foregoing Rules Indicate the General Practice in planning the illumination of a room. It must be said, however, that this set of rules must not be followed too slavishly. In illumination no rules can take the place of judgment and intelligence. Each project must be considered more or less as a problem by itself, for which previous experience and former installations should be made to furnish data and to suggest methods. It is well, therefore, when planning the illumination of a room, to visit as many similar rooms as possible, note the effect of the systems in use and obtain data as to their efficiency, cost, etc. The most successful scheme may then be used as the basis for planning the desired installation.

Example. To design the lighting system for a drafting-room 25 × 63 ft with a 13-ft ceiling.

(1) According to Table IX, good practice is to use 25 lumens/ft² for drafting-rooms.

(2) It is necessary that the light be unusually well diffused so that annoying shadows will not be cast on the work. For this reason we shall use a totally indirect system. The unit decided upon is No. 14 (Table VI).

(3) Since the ceiling height is 13 ft, a spacing between units of 13 ft is permissible (Table X). Using 12½ ft spacing and 6½ ft between outlets and walls, we get 10 outlets in 2 rows of 5 each.

(4) The room index, according to Table V, is 2.5. The walls and ceiling must be light to get good results with an indirect system. Using a very light ceiling and fairly light walls, we obtain 0.34 for the coefficient of utilization and 0.60 for the average depreciation factor (Table VI).

Thus the total luminous output of the lamps must be by Equation (4):

$$F = \frac{25 \times 63 \times 25}{0.34 \times 0.60} = 193\,000 \text{ lumens}$$

(5) Since there are 10 lamps, the luminous output of each one must be 19 300 lumens. The 1 000-watt lamp gives 20 400 lumens (Table IV), which should be satisfactory. Thus we use 10 indirect units with 1 000-watt lamps and obtain slightly over 25 lumens/ft² of very even and well-diffused light.

A Few Modern Designs. With modern high levels of illumination, direct lighting of the ordinary type is very likely to produce glare as well as harsh shadows and uneven illumination. These defects can be eliminated by using

DIFFUSING GLASS of sufficient area in front of the lamps. Many modern installations of the highest class use large WALL-PANELS or SKYLIGHTS of etched glass, or other diffusing glass, and obtain a very pleasing effect and absence of glare.

COVE LIGHTING is also frequently used to supply a major part of the light This can be supplemented if desired by ornamental luminaires hung from the ceiling or by torchiers on the walls, the purpose of these being to add a touch of color or to give variety to the lighting rather than to add materially to the level of illumination. In this way all luminous surfaces are of low brightness and all traces of glare are banished.

An example of the latter method is the FUR SALON of L. BAMBERGER & COMPANY, Newark, N. J. Here cove lighting is used, 25-watt daylight lamps being placed on 9-in centers and concealed behind a serrated molding near the ceiling. Modernistic etched-glass wall-panels and luminaires by Siegel of Paris give a decorative effect. A total of 11 000 watts of daylight lamps produces an average illumination of 5 lumens/ft². The room is 27 × 63 ft.

THE QUOTATION-BOARD ROOM OF THE SAN FRANCISCO STOCK EXCHANGE is another example of thoroughly modern treatment. This room is 122 ft long, 68 ft wide, and has a 40-ft ceiling. There are no pendant fixtures, but in the center of the ceiling there is a panel 109 × 39 ft made up of metal and hammered glass. Above this panel are fifty-five 750-watt lamps and twenty 300-watt lamps in prismatic glass reflectors. The resulting illumination in the room is 30 lumens/ft², and is very well diffused The board itself is illuminated to 75 lumens/ft² by a special trough containing 150-watt lamps on 8½-in centers.

Daylighting of Interiors

Until recently the problem of daylight illumination of buildings received but little attention. Too often windows were placed purely by guess, and the resulting illumination was highly uneven and inadequate. Mistakes of this type are difficult to remedy.

Within the last few years, however, considerable research has been made on the calculation of daylighting and on the best size and location of windows. The method has been used recently in the design of new buildings for General Motors, the General Electric Company, Western Electric Company, and others, and has resulted in a marked improvement in the quality and quantity of illumination.

Case I. Window Perpendicular to Working-Plane. It has been shown by Higbie * that a window of uniform brightness of B candles/ft² will produce an illumination at a point P of

$$E = \frac{B}{2}\left[\tan^{-1}\frac{m/f}{\cot\gamma} - \frac{\cot\gamma}{\sqrt{\cot^2\gamma+1}}\tan^{-1}\frac{m/f}{\sqrt{\cot^2\gamma+1}}\right] \quad \text{(lumens/ft}^2\text{)}$$

in which m = width of window (feet);
f = height of window (feet);
γ = vertical angle subtended by window.

Values of illumination are given in Table XII for a window brightness of 200 candles/ft². This is a representative value for a dull day. The table applies directly only when the bottom of the window is on the level of the working-plane and the point P is on a perpendicular to the window as shown in Fig. 4 By a slight modification, however, the table can be applied to any case.

* See Bibliography at end of chapter.

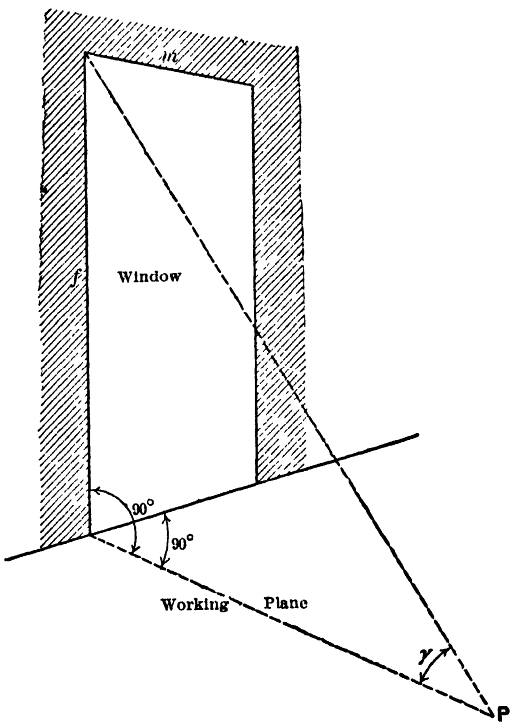

Fig. 4. Illumination from Vertical Window

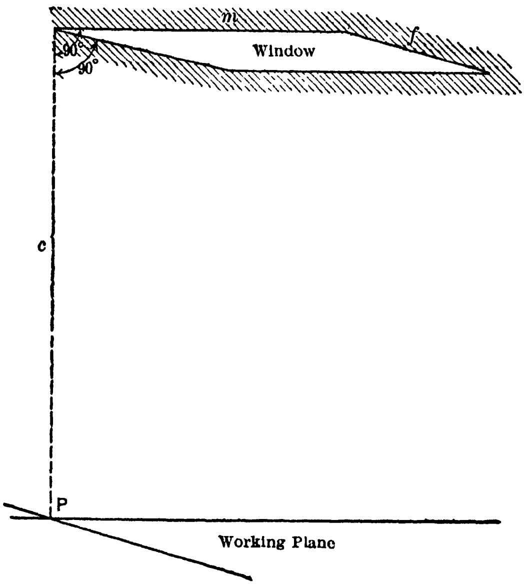

Fig 5 Illumination from Horizontal Window

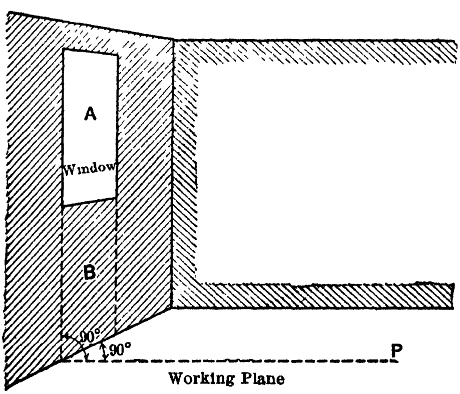

Fig. 6. Illumination from Window A.

Table XIII gives the illumination for any size window of brightness 200 candles/ft².

Other Positions of Windows. Tables XII and XIII apply directly only to the illumination at points on a perpendicular erected at a corner of the window. The question immediately arises as to the illumination at other points. This can be found very easily as shown below.

Consider the illumination at P (Fig. 6) where the bottom of the window A is not on the level of the working-plane. First take the fictitious window AB. Table XII applies, and the illumination is quickly obtained. Next the value for the fictitious window B is determined. The true illumination at P is then the difference of the two, or:

(Illumination at P due to A)

= (Illumination due to AB) − (Illumination due to B).

Similarly for the window AB of Fig. 7:

(Illumination at P due to AB)

= (Illumination due to BD) − (Illumination due to D)

+ (Illumination due to AC) − (Illumination due to C).

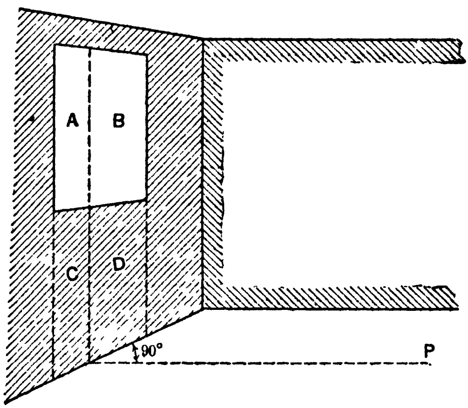

Fig. 7. Illumination from Window AB

If much work of the kind is to be done, it is advisable to plot a set of curves from Tables XII and XIII. Then from a blue-print of the room, the angle γ can be read by means of a protractor, the values of m and f can be scaled off, and the illumination at any point determined.

Artificial Windows. The method is also applicable to artificial lighting from skylights, modernistic panels, indirectly lighted ceilings, etc. In such cases the values of the table must be multiplied by the ratio of the actual brightness of the source to 200 Thus if the source has a brightness of 50 candles/ft², the values of the table must be multiplied by 50/200 = 0.25.

Example. A room is illuminated by an artificial skylight 8 × 16 ft made of diffusing glass and evenly illuminated from above by incandescent lamps to a brightness of 100 candles/ft². What is the illumination on a desk directly beneath the center of the skylight and 12 ft below it?

Table XIV. Illumination from Vertical Side-Wall Windows *

$C = 0.87\,(A + B)$

Here the window must be considered as made up of four equal parts in order to get the desk beneath the corner of each part. For one section:

$$\begin{aligned} m &= 8 \\ f &= 4 \\ m/f &= 2.0 \\ c &= 12.0 \\ c/f &= 3.0 \end{aligned}$$

Table XIII gives 16.5 as the illumination due to such a 4 × 8-ft window with a brightness of 200 candles/ft². For the entire 8 × 16-ft window, the illumination on the desk would be four times this or 66.0 lumens/ft². But the actual brightness is not 200 candles/ft² = it is only 100. Thus the actual illumination on the desk is

$$66.0 \times 100/200 = 33.0 \text{ lumens/ft}^2$$

The Fenestra Method. The above is a general method applicable to many problems. For the special cases most used in practical daylighting, Randall and Martin * have formulated tables which give directly the daylight illumination due to windows of brightness 200 candles/ft².

Table XIV gives the illumination on a working plane which is at the level of the bottom of the window. It applies to steel-sash windows with clear or hammered glass having a transmission factor of 80%. The windows should have an almost unobstructed length of 200 ft or more. For any number of panes 20 in high, and for any distance from the window, the illumination is read directly from the table. In case the window is less than 200 ft long, a correction is applied (Fig. 8). Also if the window is dirty another correction (Fig. 9) is used.

Table XV gives the illumination from vertical monitor windows. It is used exactly like Table XII.

Table XVI and **Table XVII** are for sloping monitor windows. Here it should be noted that the distances are measured from the PLANE OF THE WINDOW; that is, from the point C on the working plane.

Example. A steel-sash window is 6 panes high (10 ft 3 in) and 20 ft wide. What is the illumination at a point P on the level of the bottom of the window and 15 ft from it?

From Table XIV the illumination from a 200-ft window is found to be 31.0 lumens/ft². However, the window is only 20 ft wide, so Fig 8 must be used. This gives a factor of 0.38. So the actual illumination at P is

$$31.0 \times 0.38 = 11.8 \text{ lumens/ft}^2$$

This is for a clean window. After two months' use, we could expect

$$11.8 \times 0.72 = 8.5 \text{ lumens/ft}^2$$

by use of Fig. 9.

It will be noted that the Higbie method and the Fenestra method are based upon slightly different postulates. The Higbie method depends upon a theoretical treatment which assumes that the windows are of uniform brightness throughout, while the Fenestra method is based largely upon actual measurements made in buildings. In case prismatic glass is used, both methods will probably give values which are low for long distances from the

* See Bibliography at end of chapter.

window, since it is the function of such glass to throw the light far into the room.

The Diffusion of Light through Windows*

Tests on the Diffusion of Light by Glass.† The results of tests on a score or more of different glasses may be stated briefly. We may increase the light in a room 30 ft or more deep to from three to fifteen times its present value by

* See, also, the subjects Pressed Prism-Plate Glass and Prism Glass.
† From Report No. III, Insurance Engineering Experiment Station.

using FACTORY-RIBBED GLASS instead of PLANE GLASS in the upper sashes. By using prisms we may, under certain conditions, increase the effective light fifty times. The gain in effective light on substituting ribbed glass or prisms for plane glass is much greater when the sky-angle is small, as in the case of windows opening upon light-shafts or narrow alleys. The increase in the strength of the light directly opposite a window in which ribbed glass or prisms have been substituted for plane glass is at times such as to light a desk or table 50 ft from the window better than one 20 ft from the window had previously been lighted.

The Kinds of Glass Tested were as follows:

(1) Ground glass of different degrees of fineness.

(2) Rough plate or hammered glass

(3) Ribbed or corrugated glass, with five, and eleven and twenty-one ribs to the inch, the corrugations being sinusoidal in outline, as in *A*, Fig. 10, and the back of the plate smooth.

(4) Glass known as MAZE, FLORENTINE or FIGURED, in which a raised pattern is worked upon one side, practically roughening the whole surface.

(5) Wash-board glass, corrugated, with twenty-one ribs to the inch on one side and five ribs to the inch on the other side, the ribs being parallel.

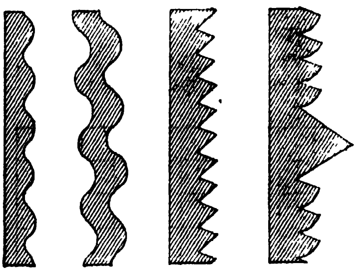

Fig. 10. Types of Ribbed or Prism-glass

(6) Skylight-glass, which has five ribs to the inch on each side, the groove on one side being opposite the rib on the other, giving a sinuous section *B*, Fig. 10.

(7) Ripple-glass, with rippled surfaces on both sides; of very beautiful appearance and a clear white color.

(8) Glass ribbed on one side and figured on the other.

(9) Ribbed glass with a wire net pressed into it, to increase its resistance to fire.

Of these several specimens, one or two may be dismissed with brief mention. Ground glass is of little value, except as a softening medium for bright sunlight. Its rapidly increasing opaqueness with moisture and dust makes it undesirable as a window-glass. The common rough plate has very little action as a diffusing-medium, giving no perceptible change in the effective light. Ripple-glass has great value as a diffusing-medium in small rooms with nearly open horizon. Of the ribbed glasses, the fine Factory-Ribbed, with twenty-one ribs to the inch, is distinctly the best, not in all probability because of the fineness, but because of the greater sharpness of the corrugations. The Ribbed wire-glass is about 20% less effective than the ordinary Factory-Ribbed glass. The addition of a second corrugation upon the back of the plate giving the Skylight and Wash-Board glass is of no apparent value. The raised pattern imprinted upon one surface of the glass, as in the case of the Maze glass, gives the widest diffusion, especially in bright sunlight. A raised figure, when worked upon the back of the Ribbed glass, renders it less offensive to the eye in bright sunlight, but less effective in deep rooms. The only glasses of this group which it is worth while, then, to discuss further are the Factory-Ribbed and the Maze glass. The second group comprises various prism glasses (Fig. 10).

Conclusions. (1) The conditions in a room less than 15 ft deep are such that, except with a skylight of less than 45°, it is not advisable to alter the general course of the light by using a prismatic or ribbed glass. A nearly hemispherical diffusion, such as is given by the Maze or Ripple-glass, is ordinarily preferable.

(2) When a room is from 20 to 60 ft deep, or even more, and has a skylight of 60° or less, the ribbed and prismatic glass results in a very great gain in effective light. The gain in brilliancy is such as to make a basement with prism-canopies as light as a second story with plane glass.

Rooms with windows opening upon light-shafts and narrow alleys with very limited openings to the sky, where the available light is now small, may have the light 20 ft back from the window increased ten or twenty times by using prisms; and, by using canopies of prisms, it is sometimes possible to strengthen the light fifty to one hundred times. With sky-angles of 30°, or less, and in deep rooms, the relative efficiency of the prism tile increases greatly. The refraction of the incident ray in a case of the ribbed glass and prism is shown in Fig. 11. Ribbed and maze glass are of very great value in softening the light, especially in the case of such windows as are exposed to the direct sun, aside from their effectiveness in strengthening the light at distant points. With the Maze glass, the artist may have, in all weather and in all directions, what is in effect a much-desired NORTH LIGHT. The photographer may have in this way as well diffused a light as he now has with cloth screens or shades, and with a much greater intensity. To be efficient in rooms 20 ft deep or more, ribbed glass should be set with its ribs horizontal, and where the sunlight falls upon it, it should be provided with thin white shades. All inferences drawn from the test are made upon the assumption that the windows are to be glazed with diffusing glass only in the upper half, which is the common practice. If the lower sash is to be glazed with diffusing glass as well, a further increase of about 25% may be expected.

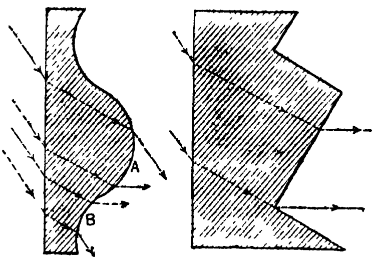

Fig. 11.—Refraction of Light in Ribbed and Prism-glass

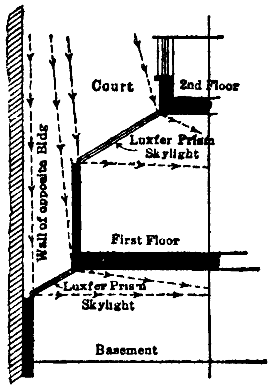

Fig. 12. Basement and First Story Lighted from Court

Considering both expense and efficiency, the following general suggestions are given: Use Maze or Ripple-glass in small rooms or offices not more than 15 or 20 ft deep; use Factory-Ribbed glass in rooms from 30 to 50 ft deep, with sky-angles of 60° or more; use prisms or Factory-Ribbed glass, in sheets, in all vertical windows in rooms more than from 50 to 60 ft deep, with sky-angle of less than 45°. With a sky-angle of less than 30° use prisms in canopies. Fig.

12 shows an effective method of lighting the basement and first story where the light must come from a court.

Floodlighting of Buildings

Floodlighting provides a means of revealing and emphasizing architectural beauty which would otherwise be hidden at night. The method has been made economically feasible by modern high-efficiency lamps.

For buildings of simple construction it is usually most effective to illuminate the entire front more or less UNIFORMLY. Any marked variation in illumination from point to point (SPOTTY illumination) must be avoided. This means that the number of floodlight projectors must be adequate, the beams must not be too concentrated, and the projectors must be carefully adjusted to give the best effect. A GRADUAL INCREASE in illumination from bottom to top, so that the upper part of the building stands out in contrast with the background, is effective. Usually the projectors can be placed on nearby buildings at a distance of 50 to 200 ft.

For the setback type of construction floodlighting seems particularly adaptable. The projectors are placed just inside the parapet and a foot or two above the roof level. The units can be arranged to give either a uniform illumination over the setback section or to give a gradual variation in illumination from top to bottom. The projectors should be carefully adjusted after installation to give the most pleasing result. Different colors can be employed advantageously on the different sections by the use of colored glasses in the floodlight units.

Equipment. Floodlight projectors may be divided into two general classes, the NARROW-BEAM type, using concentrated-filament projection lamps and carefully designed reflectors; and the MEDIUM AND BROAD BEAM types, using ordinary lamps. The former finds its principal use in lighting statues, columns, and other features where a broad beam would result in much wasted light. For most purposes, however, the ordinary type of lamp in a medium-beam reflector is recommended.

The control of light is done almost entirely by the REFLECTOR, the front glass being used largely to make the unit water-tight and dust-proof. Reflectors are made of various materials, as shown in Table XVIII.

Table XVIII. Reflection Factors of Various Metals

	Per cent
Silver plate	92
Silvered glass	82–88
Chromium plate	65
Polished aluminum	62
Nickel plate	55

Silver-plated metal reflectors are the most efficient when new, but are never used in floodlights because they quickly tarnish. Silvered glass is very efficient and is widely used. Chromium is finding considerable use because of its freedom from corrosion and its ability to stand rough usage which would ruin glass reflectors. However, it will be noted that it reflects much less light than silvered glass.

COVER-GLASSES are usually of clear heat-resisting glass which is clamped between asbestos gaskets to make a water-tight unit. In some cases, lightly

stippled glasses are used to give a more diffused beam. COLORED GLASS FILTERS are available in red, amber, green, and blue; and by combination of projectors with glasses of different colors any tint can be obtained on the floodlighting surface.

Design of a Floodlight Installation. Table XIX gives RECOMMENDED VALUES OF ILLUMINATION to be used in floodlighting installations for down-town buildings in cities of various size. It will be noted that in small cities a lower level of illumination is permissible than in larger cities. This is due to the lower illumination usually found in streets and store windows in the smaller cities and the smaller number of electric signs. If the building to be floodlighted is in an outlying section of a large city, the conditions are much as they are in smaller cities, and the column for the next smaller size city should be used.

Table XIX applies to white light. If the lighting is to be done in COLOR, the wattage must be increased to take into account the absorption of light by the colored glass. The watts should be increased approximately as follows:

Amber	50%	increase in watts
Red	100%	increase in watts
Green	200%	increase in watts
Blue	400%	increase in watts

Table XX gives the LUMINOUS OUTPUT of various floodlight projectors. The results are given in lumens in the main beam of light, the spill light being neglected. For most purposes the medium-beam projectors using general-service lamps are best.

Table XXI gives the luminous outputs of various lamps used in flood-lights. The general-service lamps have a life of 1 000 hours, and may be burned in any position, while the floodlight lamps have a life of 800 hours and must not be burned within 45° of the vertical, base up.

Table XIX. Recommendations for Floodlighting *

Representative building materials	Initial reflection factors, per cent	Foot-candles for down-town † buildings in cities of population: 50 000 or over	50 000 to 5 000	Under 5 000
White terra-cotta Cream terra-cotta Light marble	60–80	10	8	6
Light gray limestone Bedford limestone Buff limestone Smooth buff face brick	40–60	15	12	8
Briar hill sandstone Smooth gray brick Medium gray limestone Common tan brick	20–40	20	15	10
Dark field gray brick Common red brick Brownstone	10–20	30	20	15

* Taken from Edison Lamp Works Bulletin LD-159.

† For buildings in outlying districts use the foot-candles recommended for down-town buildings in cities of the next smaller classification.

NOTE. Buildings composed of material having a reflection factor less than about 20% cannot economically be floodlighted unless there is a large amount of light trim.

Table XX. Beam Lumens of Typical Floodlighting Units *

Beam spread	Projectors designed for floodlight lamps †		Projectors designed for general-service lamps

	500	2 900	1 000	7 400	8 800
			1 500	.	13 000

* Taken from Edison Lamp Works Bulletin LD-159.

† These lamps have concentrated filaments and can be burned in any position except within 45° of the vertical, base up

‡ These large units are recommended for long throws, or where the installation will be kept in operation for at least five years, or where there are unusually severe operating conditions.

Table XXI. Lumen Outputs of Mazda Lamps for Floodlighting Service

	General-service lamps (rated life 1000 hr)					Floodlight lamps (rated life 800 hr)	
Lamp watts .. .	300	500	750	1 000	1 500	250	500
Approximate lumens.....	5 400	9 850	14 700	20 400	32 400	3 575	8 300
Lumens per watt. .	18 0	19.7	19 6	20 4	21 6	14.3	16.6

Procedure in Design. (1) Decide upon how much of the building is to be floodlighted and where projectors are to be placed.

(2) Obtain lumens/ft² from Table XIX.

(3) Assume size of projectors (500 watt is used perhaps more than any other size). Obtain beam lumens from Table XX.

(4) Determine the number of projectors by use of the formula:

$$\text{Number of projectors} = \frac{(\text{lumens/ft}^2) \times (\text{area to be lighted})}{0.7 \times (\text{beam lumens})}$$

where (lumens/ft²) is obtained from Table XIX and (beam lumen) is obtained from Table XX. The factor 0.7 is to allow for light spilled around the edges of the building.

In most cases this will give a large number of units so that there is no question but that the projectors can be adjusted to give uniform illumination over the area in question. A method of checking for uniform coverage is given in the Edison Lamp Works Bulletin LD–159, from which the above data were obtained and to which the reader is referred for more information.

Example. The top setback section of a building in a city of 200 000 is to be floodlighted. The building is of common tan brick and the section is 30 ft high and 100 ft long on a side.

Table XIX gives 20 lumens/ft² as the illumination to be used. The area to be lighted on each side of the building is $30 \times 100 = 3\ 000$ sq ft. It is decided to use 300-watt medium-beam units with general-service lamps. Table XX gives 1 700 beam lumens as the light emitted by such a projector. Thus,

$$\text{Number of projectors} = \frac{3\ 000 \times 20}{0.7 \times 1\ 700} = 50$$

Use 50 projectors on each side of the building (200 total), and mount them just inside the parapet.

CHAPTER XXXIV

ELECTRIC WIRING

BY

W. H. TIMBIE

PROFESSOR OF ELECTRICAL ENGINEERING, MASSACHUSETTS INSTITUTE OF TECHNOLOGY

AND

P. H. MOON

ASSISTANT PROFESSOR, MASSACHUSETTS INSTITUTE OF TECHNOLOGY

General Considerations and Definitions. Electrical energy is now in common use, furnishing power, heat and light, operating bells and buzzers, and transmitting messages by telephone and telegraph. In order to accomplish these results, a current of electricity must flow around an electric circuit. The nature of electricity is not known, but the flow of it through an electric circuit is analogous to the flow of water through a system of pipes.

Current. Amperes. The flow of water is measured in GALLONS PER SECOND. The flow of electricity is measured in AMPERES. An ampere-flow of electricity is analogous to a gallon-per-second flow of water. The amperes thus indicate the quantity of electricity flowing through an electrical appliance in one second. About ½ ampere is flowing through an ordinary 60-watt, 115-volt incandescent lamp. An arc-lamp usually requires from 5 to 10 amperes.

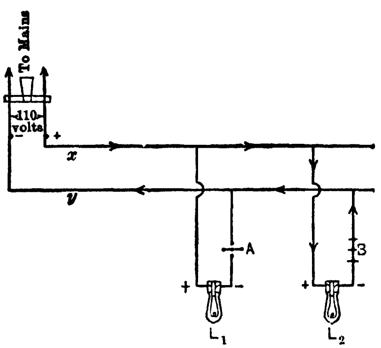

Fig. 1. Current always Flows from (+) to (−)

Pressure. Volts. When a current of water flows from one point to another in a pipe-system, it is always because there is a hydraulic pressure present causing it to flow. This pressure is usually measured in pounds per square inch. Similarly, when a current of electricity flows from one point to another in an electric circuit, it is because there is an electric pressure present which causes it to flow. This electric pressure is measured in VOLTS. An electric pressure of 1 VOLT is analogous to a hydraulic pressure of 1 lb per sq in. The pressure which causes the ½-ampere current to flow through an incandescent lamp is usually 115 volts. The electric company installs at least two wires in a residence and then maintains an electric pressure of 115 volts between them just as the water company maintains a pressure in the water-pipes. This electric pressure is at all times tending to force electricity from one wire to the other wire across the space between the two wires, just as the water-pressure

tends to force the water out from the pipe. The rubber insulation is put on to prevent this flow, very much as the strength and compactness of the iron prevents the flow of water through the walls of the pipe. But when one terminal of a lamp is connected to one wire and the other terminal to the other wire, the electric pressure tending to send a current from one wire to the other, sends a current through the lamp and causes it to glow. We mark the wire bringing the current to the lamp (+). The wire taking the current away, we mark (−). Thus in Fig. 1, if the current comes in on the wire marked (x), this wire is (+) and the wire (y) is (−). A pressure of 115 volts is maintained which tends to cause a current to flow across from the wire (x) to the wire (y). No current can flow, however, unless some path is afforded between the two wires. For instance, no current is flowing through lamp L_1, because the open switch A makes a gap across which the current cannot pass. Switch B, however, is closed, thus allowing the pressure to force a current from the wire (x) through the lamp L_2 to the wire (y) and back into the street-mains. Of course the electric company maintains the 115-volt pressure between the wires (x) and (y) whether any current is drawn from the wires or not, just as a water company maintains the pressure in the water-mains whether any water is drawn from the pipes or not.

Resistance. Ohms. The fact that a current of only ½ ampere flows through an incandescent lamp when a pressure of 115 volts is applied to it, is due to the RESISTANCE of the fine filament. This resistance of the filament is analogous to the resistance which a pipe of small bore offers to the flow of water. The resistance of an electrical appliance is merely the ratio of the pressure to the current which that pressure can force through it. As an equation, it is expressed

$$\text{Resistance} = \frac{\text{pressure}}{\text{current}}$$

When the pressure is measured in volts and the current in amperes, the resistance is then in ohms. Thus

$$\text{Ohms} = \frac{\text{volts}}{\text{amperes}}$$

Thus, since a pressure of 115 volts forces ½ ampere through an ordinary incandescent lamp, the resistance of the lamp is $115/\frac{1}{2} = 230$ ohms.

Ohm's Law. This relation between pressure, current and resistance is called OHM'S LAW. It is written in symbols in the three forms

$$R = E/I$$
$$E = IR$$
$$I = E/R$$

where R = resistance in ohms;
E = pressure in volts;
I = current in amperes.

Example. An electric flat-iron has a resistance of 35 ohms. What current will flow through it when it is put across a 110-volt circuit?

$$I = E/R = 110/35 = 3.14 \text{ amperes}$$

Example. An electric toaster takes 5 amperes when on a 115-volt circuit. What resistance does it have?

$$R = E/I = 115/5 = 23 \text{ ohms}$$

Insulators and Conductors. In order that practically no current may leak from one wire to the other, the wires are covered with rubber. This rubber covering offers such high resistance to the flow of an electric current that, although two wires may lie very close to one another with only this rubber between them, practically no current leaks through the rubber from one wire to the other. Materials such as rubber, glass, porcelain, dry wood, etc., have this resisting property and are said to be INSULATORS. Metals, on the other hand, offer very little resistance to the flow of an electric current and are called CONDUCTORS. A copper wire $\frac{1}{10}$ in in diameter has a resistance of only $\frac{1}{1000}$ of an ohm per foot. Accordingly, because of their low resistance, copper wires are generally used to carry electric currents, and because of its high resistance, rubber is generally used as a covering of the copper wires to prevent leakage from one wire to another. Wire, approved by the National Board of Fire Underwriters and installed according to their rules, will have the proper insulating covering for each installation.

Power. Watts. The flow of an electric current has been likened to the flow of water through a pipe. A current of water is measured by the number of gallons, or pounds, flowing per minute; a current of electricity is measured by the number of amperes. The power required to keep a current of water flowing is the product of the current in POUNDS PER MINUTE by the head, or pressure, in FEET. This gives the power in FOOT-POUNDS PER MINUTE. To reduce to horse-power, it is necessary merely to divide by 33 000. Thus

$$\frac{(\text{pounds per minute}) \times (\text{feet})}{33\,000} = \text{horse-power}$$

In exactly the same way, the POWER required to keep a current of electricity flowing is the product of the current in AMPERES by the pressure in VOLTS. This gives the power in WATTS.

$$\text{Watts} = \text{amperes} \times \text{volts}$$

The term WATT is merely a unit of power, and denotes the power used when one volt causes one ampere of current to flow. The watts consumed when any given current flows under any pressure can always be found by multiplying the current in amperes by the pressure in volts. Thus, if an incandescent lamp takes 0.5 ampere when burning on a 110-volt line, the power consumed equals

$$0.5 \times 110 = 55 \text{ watts}$$

That is,

$$\text{Power} = \text{current} \times \text{pressure}$$

or

$$\text{Watts} = \text{amperes} \times \text{volts}$$

Example. What power is consumed by a motor which runs on a 220-volt circuit, if it takes 4 amperes.

$$\text{Watts} = \text{amperes} \times \text{volts} = 4 \times 220$$
$$\text{Power} = 880 \text{ watts}$$

Incandescent lamps are rated as to the voltage of the line on which they can run, and also as to the amount of electric power it takes to keep them glowing. Thus, a lamp may be rated as a 110-volt, 50-watt lamp. Another lamp may be rated as a 110-volt, 25-watt lamp. This means that both lamps are intended to run on a 110-volt circuit, but the first takes twice as much power as the second.

The Power-Equation. The above relation between volts, amperes and watts is usually expressed in the form of an equation:

$$P = IE$$
$$I = P/E$$
$$E = P/I$$

in which P = power in watts;
I = current in amperes;
E = pressure in volts.

Example. What current does a 40-watt tungsten-lamp take when running on a 115-volt circuit?

$$I = P/E = 40/115 = 0.348 \text{ ampere}$$

Power. Kilowatt and Horse-Power. Because the watt is so small a unit of power, being only 0.74 ft-lb per second, a larger unit, the kilowatt, is generally used in connection with machines, etc.

$$1 \text{ kilowatt} = 1\ 000 \text{ watts} = 1\tfrac{1}{3} \text{ horse-power}$$

Thus a motor drawing 10 amperes from a 220-volt line would take $10 \times 220 = 2\ 200$ watts $= 2\ 200/1\ 000 = 2.2$ kilowatts.

At 80% efficiency this motor would give out 80% of $2.2 = 1.76$ kilowatts $= 1.76 \times 1\tfrac{1}{3} = 2\tfrac{1}{3}$ horse-power.

Horse-Power-Hour. Kilowatt-Hour. When a man buys mechanical power to run machinery, he has to pay not only according to the horse-power he uses but also according to the number of hours he uses the power. For instance, he may use 40 horse-power for 1 hour and pay $1.20 for it, that is, at the rate of 3 cts for each horse-power-hour. If he uses 40 horse-power for 2 hours he would have to pay twice as much, because he has used the same power twice as long. Another way of stating the same fact is to say that he used twice as many horse-power-hours. For in the first instance he used 40×1, or 40-horse-power-hours, and in the second 40×2, or 80 horse-power-hours. In other words, he did twice as much work in the second case as he did in the first, or received twice as much energy. The unit of work or energy, then, is the HORSE-POWER-HOUR, and is the work done in 1 hour by a 1-horse-power machine.

Example. How much work is done by a machine delivering 15 h.p. when it is run for 8 hours?

1 h.p. in 1 hr does 1 h.p.-hr
15 h.p. in 1 hr does 15 h.p.-hr
15 h.p. in 8 hr does 8×15, or 120 h.p.-hr

That is

$$\text{Work} = \text{horse-power} \times \text{hours}$$

or

$$15 \times 8 = 120 \text{ h.p.-hr}$$

Similarly, electric power is sold by the KILOWATT-HOUR. This unit is the work or energy delivered in one hour by a 1-kilowatt machine.

For lighting purposes electrical energy is usually sold for from 6 to 10 cts per kilowatt-hour. Thus at 10 cts per kw-hr the monthly bill for burning a 40-watt lamp on an average of 5 hours per day would be computed as follows:

For 1 month of 30 days the lamp is burning

$$30 \times 5 = 150 \text{ hours}$$

To use a 40-watt lamp 150 hours consumes

$$40 \times 150 = 6\,000 \text{ watt-hours} = 6\,000/1\,000 = 6 \text{ kilowatt-hours}$$

At 10 cts per kw-hr, 6 kw-hr cost

$$6 \times 10 = \$0.60$$

An instrument called a KILOWATT-HOUR METER is placed in each house to measure the number of kilowatt-hours which each customer consumes. See *M* in Fig. 11 for location of Kilowatt-hour meter, and Fig. 16 for method of connection in typical installation.

Heating-Effect of Current. An electric current always heats the material through which it passes. Examples of this are the incandescent lamp, in which the current heats the fine tungsten wire until it glows; the electric heaters for chafing-dishes, toasters, etc. Even the wires carrying the current to and from the lamps are heated by the passage of the current through them. But since the heating effect for a given current is directly proportional to the resistance of the conductor, and the conductors always have very little resistance, the heating here is very slight indeed. If conductors of smaller size, and therefore of a higher resistance, were used, the heating would be very pronounced; in fact, it would soften the rubber insulation and might even produce a temperature high enough to set fire to the building. For this reason The National Board of Fire Underwriters issues a table specifying the size of wire which must be used for each amount of current. If smaller wire is used, the resistance of it might be great enough to raise the temperature to a dangerous degree. On the other hand, if a greater current than allowed by this table is sent over the wire, the temperature will also rise, because the heating of a current is also directly proportional to the SQUARE OF THE CURRENT. Thus, doubling the current which a certain wire is carrying will quadruple the amount of heat which the wire must dissipate. For this see Table III and IV.

Fuses and Circuit-Breakers. Use is made of the heating effect of a current to protect a circuit against too much current, very much as a boiler is protected by a safety-valve against too much pressure. A small piece of fusible metal, generally a mixture of lead and bismuth, is inserted in the circuit in such a way that all the current which passes through the circuit must also pass through this piece of metal. This device is called a FUSE. Any current which would be dangerous to the circuit melts this fuse, opens the circuit at this point, and thus protects the rest of the circuit from the effects of the current. The cause of the large current may be then removed and a new fuse inserted in place of the old one. CIRCUIT-BREAKERS are also used to protect a circuit against too much current. They are AUTOMATIC SWITCHES controlled by an electro-magnet and are made in a variety of styles. They operate upon the principle that when an electric current passes through a coil of wire it makes a magnet of the coil. The coil is so adjusted that when a current of a certain number of amperes passes through it, it attracts to itself a small piece of iron. The motion of this piece of iron opens the circuit. Fuses and circuit-breakers are thus AUTOMATIC SAFETY-DEVICES required for the protection of all constant-potential systems whatever the voltage. Both are for the purpose of protecting the wires from damage due to the presence of too much current from any cause whatever. A FUSE CUT-OUT or CIRCUIT-BREAKER is required at or near the place where the wires enter a building, and every branch circuit must be protected by a cut-out. Circuit-breakers are more expensive than fusible cut-outs, and are generally used only on SWITCHBOARDS for large installations.

Dynamo-Electric Machines. There are three classes of dynamo-electric machines:

(1) GENERATORS for generating an electric current.
(2) MOTORS for converting electrical into mechanical energy.
(3) TRANSFORMERS and ROTARY CONVERTERS.
  (*a*) Transformers for converting one voltage into a higher or lower voltage. Converters and transformers belong to the same class.
  (*b*) Rotary converters for changing alternating currents to direct currents or vice versa.

GENERATORS are of two general classes, namely, continuous-current and alternating-current machines; the latter are commonly called ALTERNATORS. Generators and motors of all kinds vary in voltage, current and speed, according to the purpose for which they are designed. A TRANSFORMER consists essentially of two coils of wire wound upon an iron core. Its function is to convert electrical energy from one voltage to another. If it reduces the voltage it is known as a STEP-DOWN transformer, and if it raises it, it is known as a STEP-UP transformer. A transformer has no moving parts and requires no attendant.

Kinds of Currents Produced. There are two kinds of electrical currents commonly used for light and power in building: (1) DIRECT CURRENTS, and (2) ATERNATING CURRENTS.

"A direct current is uniform in strength and direction, while an alternating current rapidly rises from zero to a maximum, falls to zero, reverses its direction, attains a maximum in the new direction and again returns to zero. A complete set of these changes is called a CYCLE. The number of times the current goes through these changes during each second is called the FREQUENCY of the current. The frequency commonly used for incandescent lighting is 60 cycles per second; that is, the current goes through the above changes in value 60 times per second. A frequency of 25 cycles is also used, especially for motors, although it is not so satisfactory for use with incandescent lights. If a direct current is likened to the steady flow of water through a pipe-system an alternating current may be likened to the rapid surging back and forth of water in a pipe-system. The advantages of alternating over direct currents are: (1) Greater simplicity of dynamos and motors, no commutators being required in some types; (2) the feasibility of obtaining high voltages by means

Table I. Average Current Taken by Direct-Current Motors

Horse-power	Amperes on 110-volt line	Amperes on 220-volt line	Horse-power	Amperes on 110-volt line	Amperes on 220-volt line
¼	3	1.5	25	186	93
½	5.4	2.7	30	222	111
1	9	4.5	35	260	130

7½	58	29	75	...	275
10	76	38	85	....	312
15	114	57	100	.....	366
20	150	75	....		....

of transformers for cheapening the cost of transmission; (3) the facility of transforming from one voltage to another, either higher or lower, for different purposes." *

The current taken by single-phase alternating-current motors can be found by noting the current taken by a direct-current motor of the same size and voltage, and dividing this current by the power-factor of the alternating-current motor. To find the current taken by each terminal of a three-wire, three-phase alternating-current motor, divide the current taken by a single-phase alternating-current motor of the same size and voltage by 1.73.

Example. What current is taken by a 5-horse-power, alternating-current, 220-volt, induction-motor of 80% power-factor?

Solution. A 5-horse-power, direct-current, 220-volt motor takes 20 amperes. A single-phase, 5-horse-power, 220-volt motor of 80% power-factor takes 20/ .80 = 25 amperes.

Electric-Lighting Systems Commonly Used for Supplying the Electrical Energy to Lamps

Direct-Current, Constant-Potential Systems. The systems most used in America are:

(1) Two-WIRE SYSTEM largely used for incandescent lighting from small plants, as for a large office-building or factory. It is usually operated at 115 volts.

(2) THREE-WIRE SYSTEM used in small towns for the lighting of buildings from the public mains, usually operated at 230 volts.

Alternating-Current, Constant-Potential Systems. There are two systems:

(1) SINGLE-PHASE SYSTEM. The term PHASE is used in connection with alternating-current systems only in the sense of CIRCUIT. Thus a single-phase system means an alternating-current system sending out power from one circuit only of the generator. A three-phase system has three circuits.

(2) THREE-PHASE SYSTEM. Three or four wires are used. This system is used almost universally by large generating stations because it is the most economical in wire. (See Table II.) For a comparison of a three-wire direct current with a three-phase, three-wire alternating current, see text under this heading. An alternating current may be changed to a direct current at a substation by a rotary converter or by a mercury-arc rectifier. The latter is very generally used in garages in order to convert an alternating current into a direct current for charging storage-batteries.

Methods of Connecting Lamps. There are three ways of connecting lamps to the distribution-wires: (1) in series; (2) in parallel; and (3) in parallel series.

(1) **Lamps in Series.** Lamps are said to be connected in series when they are arranged one after the other, so that the same current flows through all the lamps. The most common example of this system is the lighting of electric cars and the stations on an electric-railway line. The voltage of such lines is usually 550 volts. Since the ordinary incandescent lamp requires but 110 volts, five of these are placed in series as in Fig. 2. Each lamp now has a pressure of 110 volts across it, and the set of five lamps requires 550 volts across it, and so can be placed across the railway supply-wires. When lamps are arranged in series the total resistance of the circuit is the sum of the resist-

* Adapted from Kent's Pocket Book

ances of the several parts, and the voltage required to force the current through a number of lamps in series is the sum of the voltages required for the separate lamps. Thus the voltage required to supply the proper current for four 52-volt lamps is 4 × 52 = 208 volts The series system requires that the same current flow through each lamp, and if one lamp burns out the circuit is broken and all of the lamps will go out, unless some provision is made for maintaining the circuit around the dead lamps.

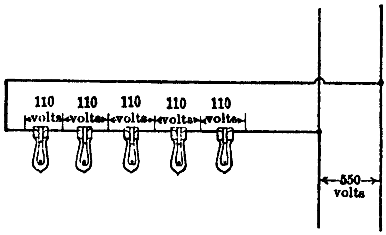

Fig. 2. Five Lamps in Series on a 550-Volt Line. Each Lamp has a Voltage of 110 Volts across It

(2) **Lamps in Parallel.** This is the common method of connecting incandescent lamps. It is illustrated in Fig. 3. With this system the pressure in each lamp is the same as in the distributing lines, and any lamp may be turned on or off without affecting the other lamps. For this system the PRESSURE or voltage must be kept constant, while the current or quantity of electricity flowing in the lines will depend upon the number of lamps that are burning. Thus if twelve 110-volt lamps are connected in parallel and each lamp takes 0.51 ampere, the total current will be 6 12 amperes, and the power required will be 673.2 watts.* With but one lamp burning, a current of only 0.51 ampere will flow. The voltage, however, must be the same for one lamp as for the twelve. For lamps in parallel, therefore, a CONSTANT-POTENTIAL system is required. The current for lamps in parallel may be turned on or off at the lamp, or a switch-loop may be run any distance and the contact made by a switch (S) as for the lower lamp (Fig. 3).

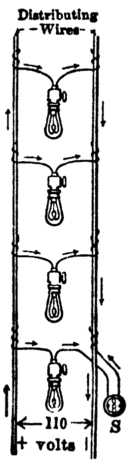

Fig. 3. Four Lamps in Parallel. Each Lamp Has the Full-line Pressure of 110 Volts across It

(3) **Lamps in Parallel Series.** This method is a combination of the other two. Parallel lines are run as in the parallel system, but two or more lamps are connected in series between them as in Figs. 4 and 5. This method of connecting lamps is used principally in places where it is desired to operate lamps on a power system. Fig. 4 shows a series of five lamps operated on a 500-volt system and Fig. 5 a series of two lamps on a 220-volt system using 110-volt lamps. Any number of series may be connected across the mains, each series being independent of the others. But in each series if one light burns out, the others in the same series will be useless, and one lamp alone cannot be used.

The Edison Three-Wire System. Figs. 3, 4, and 5 are examples of the two-wire system of distribution, which is the system recommended for average-sized office-buildings, apartment-houses, theaters and stores. Where power for motors is to be taken from the same plant as the lighting current and where the power is not too great, this two-wire system may also be used. Separate mains, however, should under all circumstances be run for the motors, as

* Watts being equal to amperes times voltage.

otherwise the variation in motor load will cause a very appreciable fluctuation in illumination. Where comparatively long lines are required and the current to be supplied is large the THREE-WIRE SYSTEM is used. By this system two voltages such as 115 and 230 can be supplied, the 115-volt circuit supplying

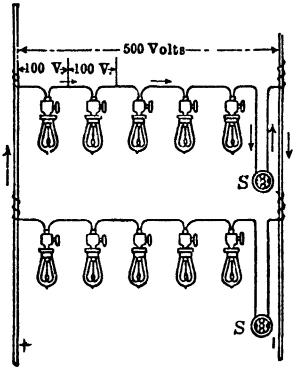

Fig. 4. Lamps in Parallel Series

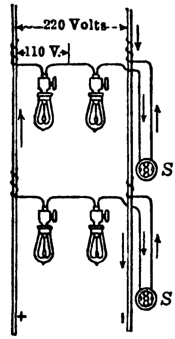

Fig. 5. Lamps in Parallel Series

the incandescent lights and the 230-volt circuit the motors. Fig. 6 shows how the wires are run and connections made. The pressure between the two outside wires is the full voltage transmitted from the generator. The current in these two wires flows in opposite directions. The middle wire, called the

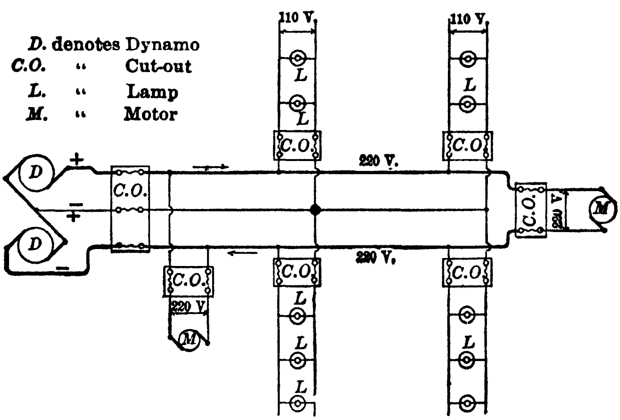

Fig. 6. Example of Three-wire System of Wiring

NEUTRAL WIRE, forms one side of two circuits, the current from one circuit tending to flow in one direction and that from the other circuit in the opposite direction; consequently, when currents of the same strength, in amperes, are flowing in both circuits they neutralize each other in the middle wire and

there will be no current flowing in this wire. With a current of 10 amperes flowing in one circuit and one of 6 amperes in the other circuit, the current flowing in the neutral wire will be 4 amperes. To obtain the greatest benefit from this system, it should always be installed so that there will be nearly the same load or number of lamps on each side of the neutral wire. Even then there will be times when more lamps will be burning on one side than on the other, so that it is necessary to give some size to the neutral wire The neutral wire is seldom made less than one-half the cross-section of the outer wires. For distributing mains in buildings having a lamp load only, the neutral wire should be of the SAME SIZE as the outer wires. From Table II it will be seen that the three-wire system effects a considerable saving in copper, amounting to fully 60% of the ordinary two-wire 110-volt system. As a rule, in supplying current for light and power from one plant, the main wires only are arranged on the three-wire system and the distributing wires are run on the two-wire system as in Fig. 6. When using the three-wire system for lighting only, the three wires are usually run no farther within the building than to the centers of distribution, and from these centers two wires are run for each circuit, the circuits being divided as equally as possible on the two sides of the three-wire system as shown by Fig. 7. Three-wire mains are now very commonly used where the current exceeds 100 amperes. When motors are operated from the three-wire system they are usually connected only to the outside wires. Motors used on three-wire incandescent-lighting systems should be wound for 230 volts.

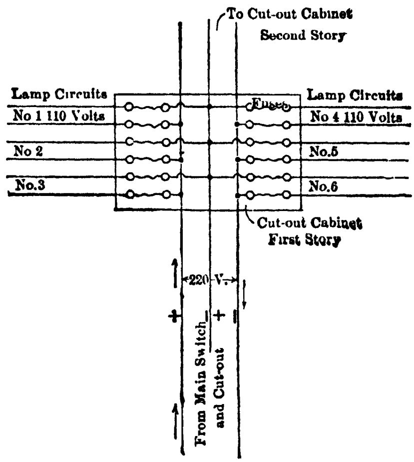

Fig. 7. The Wiring of a Cabinet

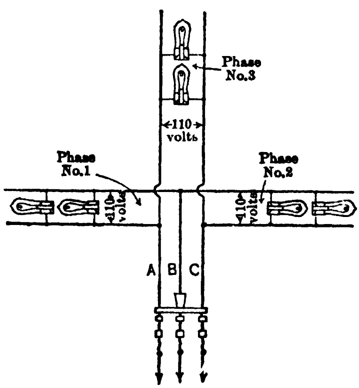

Fig. 8. Three-phase, Three-wire System, Alternating Current. Compare with Fig. 9

Comparison of the Three-Phase and Three-Wire Edison Systems. The wiring for the Edison three-wire direct-current system is the same as that

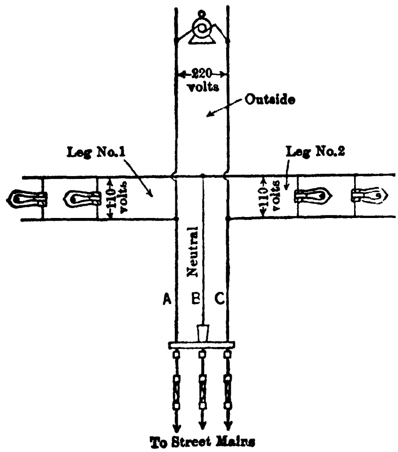

Fig. 9. Three-wire System, Direct Current. Compare with Fig 8

for the three-wire, three-phase alternating-current system, the only difference being that the voltage BETWEEN ANY TWO WIRES of a three-phase system is the same. Thus in Fig. 8 which represents a three-wire. three-phase system the voltage between the wires *A* and *B* (phase No. 1) is 110 volts; between *B* and *C* (phase No. 2) is 110 volts; and between *A* and *C* (phase No. 3) is 110 volts. But in Fig. 9, which represents a three-wire direct-current system, in which the voltage across *A* and *B*, and *B* and *C*, is 110 volts, the voltage across *A* and *C* is 220 volts or twice that across either leg.

Three-phase four-wire	0 333

Wire-Calculations

Wire-Gauges.* As the diameter of wires is ordinarily designated by the number of a wire-gauge, and as there are a number of wire-gauges in common use, some knowledge of those used for copper wire is necessary. The Brown & Sharpe, or B. & S., gauge is almost exclusively used in America in connection with electrical work, except where the size of the wire is designated in circular mils. The sizes of wire given by this gauge range from No. 0000 (0.46 in) to No. 40 (0.0031 in), but No. 14 is the smallest size permitted for interior wiring. The No. 10 wire has a diameter of about $1/10$ in and its resistance per 1 000 ft is very nearly 1 ohm. For any given number of this gauge a wire three numbers higher has very nearly half the cross-section, and one three numbers lower has twice the cross-section; thus a No. 13 wire has very nearly one-half the cross-section of a No. 10 wire, and a No. 7 has twice the cross-section of a No. 10, or four times that of a No. 13.

The Circular-Mil Wire-Gauge. In practice the B. & S. gauge is commonly used for designating wires up to No. 0 or No. 00, and all wires above that size

* For other gauges, see index.

are designated by circular mils (c.m.). The size of wire required is often determined in circular mils and designated by the corresponding B. & S. gauge-number, which is readily done by means of Table III.

The basis of the circular-mil gauge is the area of a wire $\frac{1}{1000}$ in in diameter (1 mil = 0.001 in); consequently, 1 c.m. = 0.0000007854 sq in. As the areas of circles vary as the squares of their diameters, it follows that the sectional area of a wire 2 mils in diameter = 4 c.m., of a wire 10 mils in diameter 100 c.m., and so on.

When wires are designated by circular mils, the SECTIONAL AREA and not the diameter is generally given, c.m. always referring to sectional area. The diameter of a wire in MILS OR IN THOUSANDTHS OF AN INCH = square root of its area in CIRCULAR MILS.

Thus the diameter of a wire of 3 600 c.m. = 60 mils, or 0.060 in.

The diameter of a wire 14 400 c.m. = 120 mils = 0.12 in.

The area of a wire 0 162 in in diameter, or 162 mils $= 162^2$ = 26 244 c.m.

To reduce circular mils to square inches. Multiply by 7 854 and point off ten places of decimals. Thus, 5 000 c.m. = 7 854 × 5 000 = 0.0039270000 sq in.

To obtain the sectional area of a square or rectangular bar in circular mils. Multiply together its dimensions in mils and the product by 1.273.

Example. What is the sectional area in circular mils of a bar $\frac{1}{8}$ in × $\frac{1}{4}$ in?

Solution. $\frac{1}{8}$ in = 0.125 in = 125 mils, $\frac{1}{4}$ in = 0.250 in = 250 mils; 125 × 250 × 1.273 = 39 781 25 c m.

The weight of bare copper wire per 1 000 ft = c.m. × 0.003027 lb. Thus the weight of 1 000 ft of copper wire having a sectional area of 2 000 c.m. = 0.003027 × 2 000 = 6.054 lb. Table IV gives the dimensions and weights of bare copper wire from No. 18 to No. 0000 B. & S.

Carrying Capacity of Copper Wire. The safe carrying capacity of copper wire for interior wiring is practically fixed by the underwriters, and if the capacity limits given in the table published by them are exceeded it would tend to destroy the right to recover insurance in case of fire. The safe carrying capacity of rubber-covered and weather-proof wires given by the National Board of Fire Underwriters is shown by Table III. The lower ampere-capacity assigned to rubber-covered wires is due to the fact that the rubber insulation would deteriorate in quality under a temperature as high as that allowed for weather-proof wire. No wire smaller than No. 14 may be used under insurance-rules, except that No. 16 may be used for flexible cord and No. 18 for fixture-wiring. Nos. 13, 11, 9 and 7 are not usually carried in stock and can only be purchased on special order. Rubber-covered wire must be used for service-wires, for molding-work and in damp places; it is more expensive than weather-proof wire. The latter wire may be used in open or exposed places and for outside line-wires.

Drop of Potential. When an electric current flows through a wire of any appreciable length the pressure becomes reduced by the resistance of the wire, so that if the current enters the wire at, say, 110 volts, at the extreme end of the circuit it will be somewhat less, depending upon the length and sectional area of the wire. This loss in voltage is called DROP OF POTENTIAL. Drop of potential corresponds to LOSS OF HEAD in hydraulics. As a drop of voltage materially below that for which the lamps are designed means diminished light, it is very important that the wires be proportioned so that the drop shall not be sufficient to affect the illumination. The table for safe carrying capacity for wires has nothing to do with the drop of potential which these

currents will cause in the wires. Accordingly, mains and distributing wires may be capable of carrying the number of amperes in accordance with Table II, and yet cause a drop of potential of such magnitude that the most distant lamps will burn only at a dull red. It is therefore necessary, in computing the size of these mains and distributing wires, to consider two things:

(1) That the wire is large enough, according to the underwriters' table, to carry the current safely.

(2) That the potential drop from the generator to the farthest lamp shall not be excessive.

The drop in volts (not in percentage) = current in line × resistance of line, or drop in volts = amperes × ohms.

Example. What will be the drop in a circuit of No. 14 copper wire 280 ft long, supplying nine lamps, requiring 4.5 amperes?

Solution. From Table IV it is found that the resistance of No. 14 wire is 2.527 ohms per 1 000 ft; hence for 280 ft it will be $2.527 \times 0.280 = 0.7075$ ohm, and drop in volts $= 4.5 \times 0.7075 = 3.1837$ volts. The voltage for this current (0.5 ampere per lamp) will be about 110; consequently, the percentage of drop $= 3.1837/110 = 2\frac{9}{10}\%$, nearly. A 2% drop on a pressure of 110 volts is 2.2 volts.

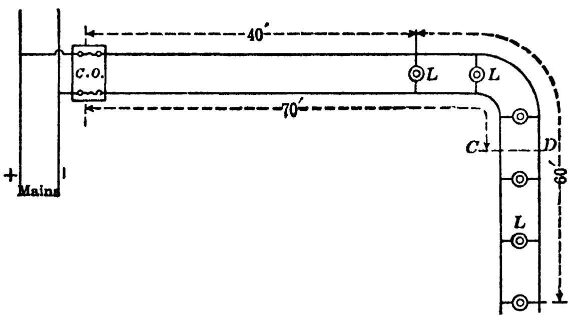

Fig. 10. The Point *D* is the Load-center

Load-Center. The meaning of this term may best be illustrated by an example. Let Fig. 10 represent a circuit carrying six lamps, the first lamp being 40 ft from the cut-out, or source of supply. The whole of the current must be transmitted through this 40 ft, but from that point it will gradually fall off, and the average current will only extend to the point *CD*, half way between the extreme lamps. Or, in other words, the load-center is analogous to the center of gravity of the lamps on the circuit. The load-center determines the length of the line in the rules for finding the necessary size of wire.

Calculations for Size of Wire for Incandescent Lighting. The sizes of wires for interior lighting are or should be always determined on a basis of a fixed drop of potential, usually 2 volts on the distributing circuit and from 2 to 3 volts on the feeders or mains.* The size of wire may be determined either in terms of its sectional area in circular mils or in terms of its resistance in ohms per 1 000 ft. Knowing the sectional area in circular mils, one may

* Many municipal lighting companies require that there shall be no more than 2% total drop in the wiring for interior lighting.

find the corresponding gauge-number from Table III, or if the resistance in ohms per 1 000 ft is known, the corresponding gauge-number may be found from Table IV.

Table III. Carrying Capacity of Wires and Cables

The formula for circular mils is as follows:

$$\text{Circular mils} = \frac{10.4 \times 2d \times N \times I}{v} \qquad (1)$$

The formula for resistance per 1 000 ft of wire is

$$\text{Resistance} = \frac{1\,000\,v}{N \times I \times 2d} \qquad (2)$$

* Approximate weight of weather-proof line-wire for outdoor work is 10% less than here given.

In both these formulas d = distance in feet, one way, from cut-out to load-center for distributing wires, or from entrance cut-out or source of current to distributing center for main lines or feeders. I = current in amperes PER LAMP. N = number of lamps supplied. v = drop in volts. Both formulas apply to any voltage and to any two-wire system. To use these formulas for the ordinary three-wire system, let N = maximum number of lamps on ONE SIDE of the neutral wire and DOUBLE THE DROP IN VOLTS. The neutral or middle wire should be of the same size as the outside wires.

Example. The distance from the cut-out to load-center of a circuit carrying sixteen 40-watt, 110-volt lamps is 50 ft. What size of wire should be used for a drop of 2 volts?

Solution. $d = 50$; $N = 16$; $I = 40/110 = 0.364$; and $v = 2$.

By Formula (1),

$$\text{Circular mils} = \frac{10.4 \times 100 \times 16 \times 0.364}{2} = 3\,030$$

Table III shows that the next larger size of wire is 4 107 c.m., equivalent to a No. 14 wire.

By Formula (2),

$$\text{Resistance per 1 000 ft} = \frac{1\,000 \times 2}{12 \times 0.364 \times 100} = 4.59$$

which we see from Table IV, is about the resistance of a No. 16 wire; but as No. 14 is the smallest wire permitted that size must be used.

To find the smallest size of wire that will comply with the underwriters' rules it is only necessary to compute the total current in amperes, and from Table III select the wire having a capacity equal to or next above the required number of amperes.

Formulas (1) and (2) may also be used for MOTOR-WIRING, if the required current in amperes is known, by substituting the given number of amperes for $N \times I$.

Table V. Wire Size Required *

(Length of wire for a circuit is double the length of run)

The difference in the cost of wiring with No. 12 instead of No. 14 is so slight, and the advantages generally sufficient, that many electrical men specify No. 12 as the minimum size for branch circuits.

This table shows the wire size required for 115-volt circuits of various lengths of run, based on a drop of two volts between the panel board and the outlets.

It is difficult in branch circuits, at least with present wiring methods, to use larger than No. 8 wire because of the difficulty of handling in conduit. Where the proper wire size for a proposed installation, according to this table, is larger than No. 8, it is usually best either to provide more circuits with less load, or to relocate distribution centers to decrease lengths of run. The dotted line shows the usual practical limits for circuit load and length of run.

Note. These recommendations on wiring are based on the allowances of The National Code: i. e. circuits equipped with medium screw sockets limited to 15 amperes and not more than 12 outlets per circuit; mogul sockets—limited to 40 amperes and 8 outlets per circuit. Present wiring practice is usually well within the limit allowed by the code. In some cases it is necessary to meet other requirements of local codes.

* From Westinghouse Lamp Co., Bulletin E-108.

† In factories it is often desirable to convert storage areas into work places to meet immediate production needs. For this reason, it is recommended that storage areas be wired according to Class B Specifications.

Example. What should be the size of the wires to be run to a motor that requires 30 amperes at 220 volts and is situated 200 ft from the distributing pole, the drop in volts not to exceed 2 %?

Solution. Using Formula (1), and substituting 30 for $N \times I$, we have

$$\text{Circular mils} = \frac{10.4 \times 400 \times 30}{4.4} = 28\,400$$

which requires a No. 5 wire. Either the watts or the current in amperes is stamped on every motor. If watts are given, the current in amperes may be found by dividing the watts by the voltage. If kilowatts are given, multiply by 1 000 and then divide by the voltage.

Wiring-Tables. Several forms of wiring-tables which are very useful to electricians are published in various books on electricity. For ordinary interior wiring Table V will show at a glance the number of wire, B. & S. gauge, required.

Simple Example of Wiring. To show the method of wiring an ordinary building for incandescent lighting we will take a two-story building having a floor-plan as shown in Fig 11. Most of the light-outlets are on the ceiling and are indicated by a small circle. The outlet marked *E* is a special outlet for heating, etc., and must be described in the specifications. Let us assume it is to take 320 watts. This is equivalent to adding eight 40-watt lamps to this circuit. *F* and *G* are wall-outlets. The meanings of the symbols used are explained under Standard Wiring Symbols. The numbers 1 and 2 inside the circles denote the number of 60-watt lamps to the outlet. The same number of 25-watt or 40-watt lamps may always be used without overloading the circuits. See Standard Wiring Symbols. The service wires should connect to the main fuse-block and switch, which should be in a small cabinet, and to the meter (*M*). The distribution-cabinet should be located near the center of the building, say at *DC*, and there should be a cabinet on each floor. From this cabinet we will run four circuits for each floor, which are indicated by the letters *A*, *B*, *C* and *D*. Circuit *A* shows the wires run for a switch on the wall near the door of each of four rooms to control the lights in those rooms. The lights on circuits *B* and *D* are not switched, except the outlet at head of stairs, which is controlled by a snap or push-button switch at *S*. For a first-class job all of the four circuits would be controlled by knife-switches in the cabinet, as shown in Fig. 12; but this is not absolutely necessary.

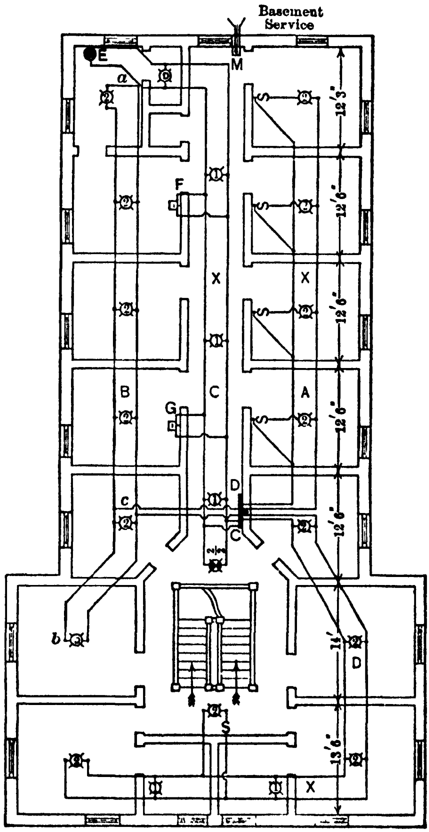

Fig. 11. Wiring-diagram for Second Story

Size of Wires. The load-center of circuits *A*, *C*, and *D* would be at about the points marked *X* (Fig. 11). For circuit *B* take one-half the distance *ab* and add to it the distance from *c* to the cabinet. In figuring the length of

line, 6 ft should be added for the drop from ceiling to the cabinet. In computing the current taken by each lamp it is assumed that no smaller than a 40-watt tungsten is used. The number of 40-watt lamps and length of wire for each circuit are as follows:

Circuit *A*, 8 lights, 41 ft one way to load-center.
Circuit *B*, 11 lights, 52 ft one way to load-center.
Circuit *C*, 16 lights, 37 ft one way to load-center.
Circuit *D*, 12 lights, 59 ft one way to load-center.
Total number of lamps, 47.

From Table V we see that all of the lamp-circuits can be No. 14 wire, which is the smallest size permitted.

Feeders. These should be run on the three-wire system. Allowing for 2 × 47 or 94 lamps in first and second stories and eight in basement, the feeders must be capable of supplying 102 lamps. Each 40-watt lamp would take 40/110 = 0.364 ampere. The distance from outside the building to distribution-cabinet is about 72 ft, allowing for three drops. Using Formula (1), and assuming that there will be fifty-one lamps on each side of the three-wire system, and doubling the drop in volts, gives

Circular mils

$$= \frac{10.4 \times 144 \times 0.364 \times 51}{4}$$

$$= 6\,960 \text{ c.m.}$$

which calls for No. 11 wire; but as this size is not carried in stock we must use No. 10. From the second story to the third No. 12 wires could be used. For almost all buildings lighted from a central station the lamp-circuits will not usually require a wire larger than No. 14, so that about the only wires which the architect needs to look after are the wires which run to the distribution-cabinets.

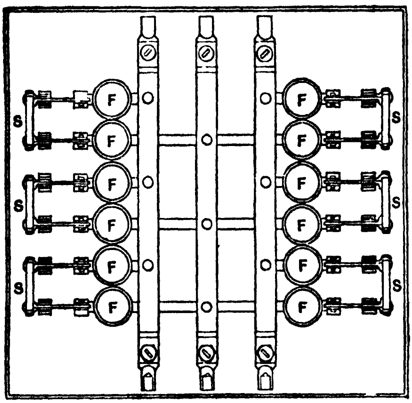

Fig. 12. Cabinet-wiring for Knife-switch Control

Switches. A switch is a device for opening or closing a circuit at will either at the fixture or at any other point. In the better class of buildings the majority, if not all, of the ceiling lights are controlled by switches placed at a convenient place on a side wall. Lights may be controlled at any distance from the fixture by running a switch-loop. For controlling either a single lamp or fixture, or any number of lamps, a switch-loop is run as shown on circuits *A* and *C*, as in Fig. 11. As shown also in Fig. 3, one side of the loop must be connected with one of the distributing wires and the other side to the lamp. When a number of lamps are to be controlled by one switch, as in the case of hall-lights, and the lamps in large rooms, such as churches, theaters, concert-halls, etc., a separate circuit is usually run for those lamps, and a

switch anywhere in one of the distributing lines will turn on or off all of the lights on that line. It is also practicable to control one lamp from two or three places. Thus by a duplex or three-point switch and proper wiring, a lamp may be lighted or turned off from either the first or second story at will. By means of two three-point switches and one four-point switch a first-story hall-lamp may be controlled at will from either the first, second or third stories. Fig. 13 shows the method of control from any number of points, since any number of 4-point snap-switches, such as *B*, *C* and *D*, can be inserted between the 3-point switches *A* and *E* if more points of control are needed. Fig. 14 shows one method of wiring for controlling a hall-light from first and second stories by means of two 3-point switches. With the switches in the position shown the circuit is broken, as there is no connection between the lamps and line *B*. By turning either switch a connection is made with line *B* and the current will flow.

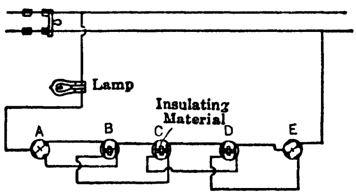

Fig. 13. The Lamp May be Turned Off or On From Any of the Five Points, *A*, *B*, *C*, *D*, or *E*

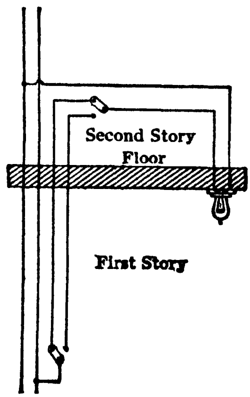

Fig. 14. The Lamp May Be Turned Off or On From Either the First or Second Story

Kinds of Switches. For controlling lamps from one point three kinds of switches are used, namely, SNAP-SWITCHES, FLUSH or PUSH-BUTTON SWITCHES and KNIFE-SWITCHES. When less than eight lamps are controlled by the switch, a flush or push-button switch is commonly used where a neat appearance is desirable, and in places where this is of no importance, a snap-switch is used, as it is the cheaper. Where a circuit of twelve or more lamps is controlled by a switch, a double-pole (d.p.) knife-switch (Fig. 15) is commonly used, being generally placed in a cabinet. Knife-switches should always be used on main wires. Snap and push-button switches are made both single and double pole. A SINGLE-POLE switch opens only one side of the circuit and a DOUBLE-POLE switch both sides. A double-pole knife-switch necessarily opens both sides. A switch used on a three-wire system may have three poles.

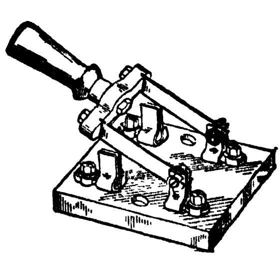

Fig. 15. Common Knife-switch

Methods of Wiring

Various wiring methods have been developed to meet different conditions:

(1) OPEN WIRING is probably the cheapest method and is still used to some extent in industrial work. In dry places and for voltages not in excess of 300, the wires must be separated $2\frac{1}{2}$ in from each other and at least $\frac{1}{2}$ in from the surface wired over. In damp locations the spacing to the surface must be increased to one inch and rubber-covered wire must be used.

(2) CONCEALED KNOB-AND-TUBE WIRING was once the favorite method of house wiring, but has now been largely superseded by armored cable and other high-class methods. The conductors are supported on porcelain knobs and are run in the hollow spaces of walls and ceilings. Wires must be rubber-covered. They must be separated at least 5 in and must be maintained one inch from the surface wired over. Where the 5-in spacing cannot be maintained, the wires are encased in lengths of approved flexible tubing.

(3) RIGID CONDUIT. Since weather-proof and rubber-covered wire cannot be run in brick walls or floors of brick, terra-cotta, or concrete without some protection other than the covering of the wires, it is necessary in such places to run the wires in tubes or conduits. In fire-proof buildings, all the wires are run in conduits or in armored cable.

For rigid conduit systems only mild steel piping of the same thickness as ordinary gas-piping is approved by the underwriters. The conduit must be continuous from outlet to outlet and must properly enter and be secured to all fittings. It is installed in the same manner as a good job of gas-fitting, except that conduit may be bent to a curve and no elbow can be used having less than a $3\frac{1}{2}$-in radius for the inner edge. Wherever branches are taken off, junction boxes must be provided, and every outlet must have an approved outlet box and plate. The wires must be No. 14 or larger, rubber-covered. The conduit system must be grounded.

Rigid conduit is undoubtedly the best form of wiring, though it is also the most expensive on account of the labor cost for bending, threading, etc.

(4) FLEXIBLE ARMORED CONDUIT is made of steel ribbon wound spirally. Its advantage over rigid conduit is that it is so much easier to install. The same outlet boxes and fittings are used as for rigid conduit, and the complete conduit system is grounded.

(5) METAL RACEWAYS are not approved for wires larger than No. 8 and must not be fused for more than 30 amps. Rubber-covered wire must be used and must be continuous from outlet to outlet. Metal raceways must be grounded.

(6) FLEXIBLE ARMORED CABLE consists of two or three rubber-covered wires protected by a spiral steel tape. It may be used in open or concealed wiring in dry locations. It may be fished and may be embedded in the plaster finish. For very damp locations, a special cable having a lead sheath under the protective armor is available. Steel covering must be grounded.

(7) NON-METALLIC SHEATHED CABLE is used only in residences or offices in residential neighborhoods. It must not be installed in masonry, concrete, or where exposed to the weather. It is comparatively cheap and easy to install.

National Electrical Code. The National Board of Fire Underwriters has prepared a code of rules and requirements for the installation of electrical lighting which is the generally recognized standard and with which all interior wiring must comply if it is desired to obtain insurance on the building. This code has also been made a part of the ordinances of most of the larger cities. The National Board of Underwriters also publishes, semi-annually, a SUP-

PLEMENT to the National Electrical Code which contains a list of all articles that have been examined and approved for use in connection with the code, together with the names of the manufacturers. Articles not included in this list will not be passed by the inspectors. Copies of the code and supplement can be obtained from the nearest Underwriters' Inspection Bureau, or by writing to the Underwriters' Laboratories, 207 E. Ohio St., Chicago; 109 Leonard St., New York; or 205 Merchants' Exchange, San Francisco. The following requirements apply to almost every installation, and every architect should be conversant with them.

Extracts from the National Electrical Code *

(1) All wire for concealed work must be of the best approved rubber-covered brands No wire smaller than No. 14 B. & S. gauge is to be used. All wire run in conduits must have double-braid covering.

(2) Where wires are concealed and run parallel to joists they must be supported on porcelain knobs which hold the wires at least 1 in from woodwork or surface wired over. Knobs must be SECURELY FASTENED and MUST BE PLACED EVERY 4½ FT. Where wires are run through joists they must be bushed with porcelain tubes the entire width of joists. All wires must be drawn tight, so as to have all slack removed.

(3) In concealed work all wires MUST BE SEPARATED FROM EACH OTHER BY AT LEAST 5 IN. Where wires run down partitions, especially partitions formed by 2 by 4-in studs, the wires must be so supported as to run in the middle of partition. If more than two wires are run down partition between studs, they must be separated by at least 5 in.

(4) Where wires pass through floors they must be protected from the floor up to a point 5 ft above the floor with conduit or with boxing. There must always be a space of 1 in between the wires and the boxing.

(5) All joints must be securely soldered and taped. A splice to be approved must be both mechanically and electrically secure without solder, but must be soldered unless made with some form of APPROVED splicing-device. Joints to be properly taped require, where rubber-covered wire is used, first to be taped with rubber tape and then with friction-tape. The insulation of a joint must equal that on the conductors.

(6) Where wires enter the building they must be provided with drip-loops.

(7) There must be a MAIN CUT-OUT AND SWITCH installed in an easily accessible place, as near as possible to the point where the wires enter the building.

General Suggestions for Electric Work †

General Principles and Recommendations. In all electric-work conductors, however well insulated, should always be treated as bare, to the end that under no conditions, existing or likely to exist, can a grounding or short circuit occur, and so that all leakage from conductor to conductor, or between conductor and ground, may be reduced to the minimum. In all wiring special attention must be paid to the mechanical execution of the work. Careful and neat running, connecting, soldering, taping of conductors, and securing and attaching of fittings, are specially conducive to security and efficiency, and

* The numbers here given do not correspond with those in the code, and several of the rules are much abridged. They are intended to give the substance, rather than the exact language.

† Preface to the National Electrical Code.

will be strongly insisted on. In laying out an installation, except for constant-current systems, the work should, if possible, be started from a center of distribution, and the switches and cut-outs, controlling and connected with the several branches, be grouped together in a safe and easily accessible place, where they can be readily got at for attention or repairs. The load should be divided as evenly as possible among the branches, and all complicated and unnecessary wiring avoided. The use of wireways for rendering concealed wiring permanently accessible is most heartily indorsed and recommended; and this method of accessible concealed construction is advised for general use. Architects are urged, when drawing plans and specifications, to make provi-

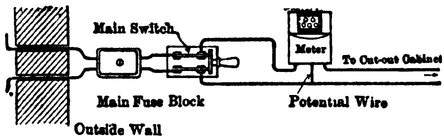

Fig. 16. Main Switch, Fuse-block and Meter Located Near the Point of Entrance of the Service-wires

sion for the channeling and pocketing of buildings for electric-light or power-wires. Fig. 16 shows a common arrangement of main cut-out, switch and meter.

Specifications for Interior Wiring *

Specifications for Interior Wiring should provide:

(1) That the wiring shall be installed in accordance with the latest rules and requirements of the National Board of Fire Underwriters, the local ordinances, and the rules of the local electric light company, where current is to be taken from the public mains.

(2) No electrical device or material of any kind to be used that is not approved by the Underwriters' National Electric Association, and all articles must have the name or trade-mark of the manufacturer and the rating in volts and amperes or other proper units marked where they may readily be observed after the device is installed.

Requirements (1) and (2) are sufficient to insure a SAFE installation.

(3) Contractor must obtain a satisfactory certificate of inspection from the city inspector or from the inspector of the local board of fire-underwriters.

(4) If the wires are to run in a conduit system it should be so specified. When a conduit system is used, THE WIRES SHOULD NOT BE DRAWN IN until all mechanical work as far as possible is completed. It is best to wait until after the plastering is dry. All conduit systems must be GROUNDED.

(5) Size of Wires. The best method is to specify the size of all wires, no wire to be less than No. 14 B. & S. gauge; but if the architect does not care to do this, the following clause is sufficient, provided he can have confidence that the contractor will comply with it: "All wires must be of such size that the drop in potential at farthest light-outlet shall not exceed 2% under maximum load."

(6) Cut-out cabinets and where they are to be placed; also location of mainline cut-out and fuse. For buildings containing not more than forty

* Wiring specifications for buildings having their own generating plant should be prepared by an expert.

lights, one distributing point is generally sufficient, although in large houses it is often convenient to have a cut-out cabinet on each floor

(7) Number and kind of switches. All outlets should be marked on the plans, and the number of lights indicated by figures 1, 2, 3, 4, etc., as in Fig. 11. See Standard Symbols. The location of all switches for controlling lights should also be indicated on the plans.

Approximate Cost of Wiring for Incandescent Lighting. Approximate estimates of the cost of wiring buildings for electric lighting are usually based on the number of outlets (not lamps). The actual cost will depend upon the number of pounds of wire required, the kind and number of switches, character of cut-out cabinets, etc., and the time required to do the work, so that a close estimate cannot be made without plans and specifications. Again, wages and prices of material vary to a considerable extent in different parts of the country, so that an estimate that would be about right for one locality would not suffice for another.

Standard Symbols for Wiring Plans

As recommended and adopted by the Association of Electragists, International, The American Institute of Architects and the American Institute of Electrical Engineers, and approved by the American Engineering Standards Committee.

	Ceiling outlet.
	Ceiling outlet (gas and electric).

CHAPTER XXXV

ACOUSTICS OF BUILDINGS

By
F. R. WATSON
PROFESSOR OF EXPERIMENTAL PHYSICS, UNIVERSITY OF ILLINOIS

Introduction. The modern science of the ACOUSTICS OF BUILDINGS began with the work of Wallace C. Sabine about 1895. In a series of fundamental, painstaking experiments, he lifted the fog of mystery that hung over the subject, and showed that action of sound in buildings could be expressed in terms of well-known scientific laws. Because of his pioneer work, and later investigations, it is now possible to prescribe conditions for securing good acoustics in any room; also, to construct walls necessary for adequate sound-proofing with some degree of success. The architectural engineer thus has available a considerable body of data for guidance in the control of acoustics in buildings. For architects, there remains an undeveloped problem in the design of auditoriums which will give conditions favorable for performers in the generation of sound and at the same time will insure comfortable listening for auditors. There are thus two chief problems in the acoustics of buildings: the ACOUSTICS OF ROOMS and SOUNDPROOFING OF ROOMS.

1. Acoustics of Auditoriums

Action of Sound in a Room. When a speaker or musician appears before an audience, the sounds he creates proceed outward in spherical waves until they strike the boundaries of the room. Here they are reflected, transmitted

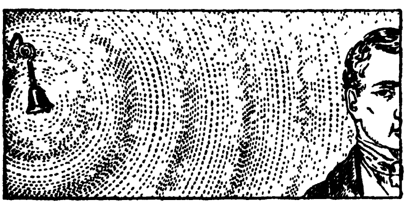

Fig. 1. Diagram Showing How Sound Travels in Compressional Waves from the Source to the Listener

and absorbed in varying amounts, depending on the character of the walls. Fig. 2 pictures a pulse of sound in a room 60 ft long and 40 ft wide, $\frac{1}{60}$ second after it has left the speaker at S. The pulse travels rapidly—as fast as a rifle bullet, about 1 120 ft per second at ordinary temperatures—so that, by successive reflections, it quickly fills the room. Fig. 3 pictures the same pulse $\frac{1}{60}$ second later than the position in Fig. 2, and shows the increasing reflections and crossings of the sound. The imagination readily supplies the details after $\frac{1}{10}$ second has elapsed, when sound has been reflected many times

not only from the walls as pictured in Figs. 2 and 3, but also from the ceiling

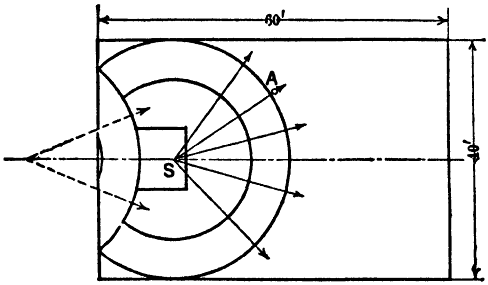

Fig. 2. Pulse of Sound in a Room, 1/60 of a Second after Leaving the Source, *S*

and floor, so that every element of volume in the room is filled with waves proceeding in every direction. This means that the sound has the same average LOUDNESS for all auditors, even those in remote corners.

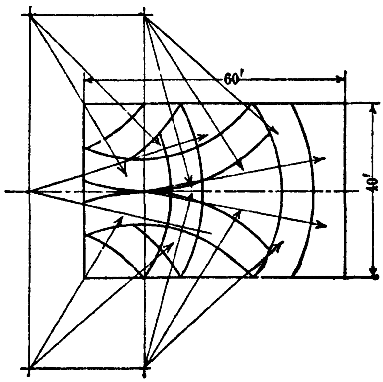

Fig. 3. Pulse of Sound, 3/60 Second after Leaving Source

Sound Waves in an Auditorium. The pulse shown in Figs. 2 and 3 is of much shorter duration than those usually met with in auditoriums. A simple musical tone, for instance, consists of a series of compressions and rarefactions that follow each other regularly. Fig. 4 is a photographic attempt to illustrate a musical sound in an auditorium. The waves pictured are really water waves. A thin metal strip, shaped so as to give a miniature outline of an auditorium, was laid flat on the glass bottom of a tank of shallow water. By directing puffs of air on the water surface, waves were generated that proceeded outward in circles and were reflected from the metal outline. Flashes of light coming up through the glass bottom of the tank cast a shadow of the waves on a screen and allowed a photograph to be taken. These water waves are quite similar in their action to sound waves and present a convenient means for studying the acoustic effect of proposed architectural features in an auditorium, so that objectionable constructions may be redesigned before the final plans are completed.

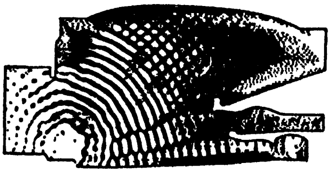

Fig. 4. Photograph Showing How Sound Waves Will Act in an Auditorium

Defects Due to Reflected Sound. While the reflection of sound has the advantage of increasing the loudness somewhat, it is also responsible for most of the acoustics defects in a room, such as ECHOES, RESONANCE and REVERBERATION. It appears of practical advantage to eliminate or reduce the reflected sound, as explained later under Ideal Auditorium Acoustics.

Echoes. When sound is reflected from a surface in the room, particularly a curved surface, auditors will get a distinct confusing repetition of the direct sound that is called an ECHO. This occurs when the time interval between

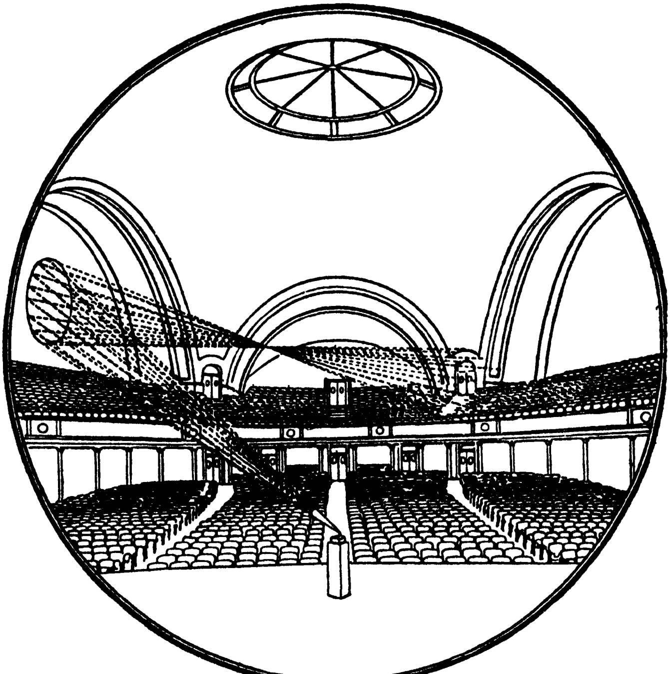

Fig. 5. Echo Set up by Reflected Sound in University of Illinois Auditorium

the direct and reflected sounds is about $\frac{1}{15}$ second or more, which corresponds to a difference in path of these two sounds of about 75 ft. Fig. 5 pictures such an echo. Curved walls are a menace to good acoustics. Fig. 6 shows a concentration of sound due to a curved wall, which will be annoying to auditors at C and D, although the difference in path between direct and reflected sound may not be great enough to produce a distinct echo. The effect of curved walls may be minimized by inserting grills in them, or by coffering them with highly absorbent material, so that the reflected sound is broken up.

Reverberation. The chief acoustic defect in rooms is a reverberation, or undue prolongation of sound. For example, when sound waves strike

plaster walls, only about 3% of the energy is absorbed, so that 97% is reflected. At the next reflection the same action follows, so that as many as 300 to 400

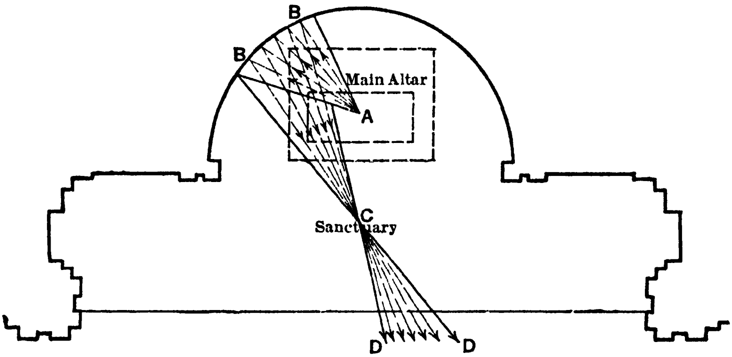

Fig. 6. Objectionable Focusing of Sound by Curved Wall

reflections may take place in a room before the sound energy is used up. The correction for this defect lies in the installation of suitable materials

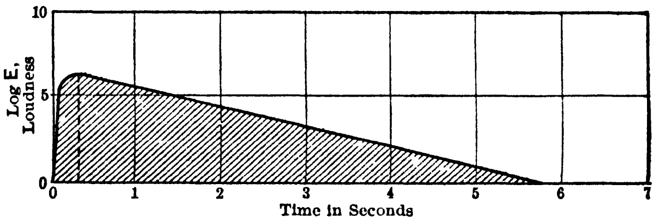

Fig. 7. Objectionable Persistence of Sound in a Reverberant Room

which absorb more energy at each reflection and cause the sound to die out more quickly. Fig. 7 gives a diagram to illustrate, and shows that the loud-

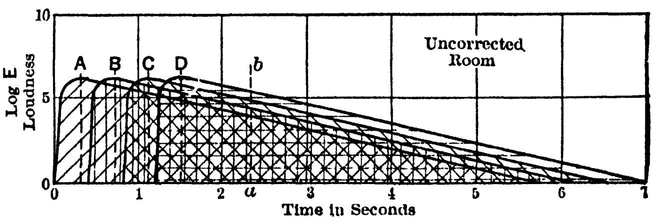

Fig. 8. Confusing Overlap of Four Words of a Speech in a Reverberant Room

ness of a spoken sound rises quickly to a maximum value in about 0.3 second, but that about 5 seconds are taken for it to die out. Fig. 8 shows the con-

fusing overlap of four words in a speech and makes clear why people are unable to understand the jumble of sounds sét up

Fig. 9 shows the same words in the same room, Fig. 8, after it has been corrected with absorbing materials.

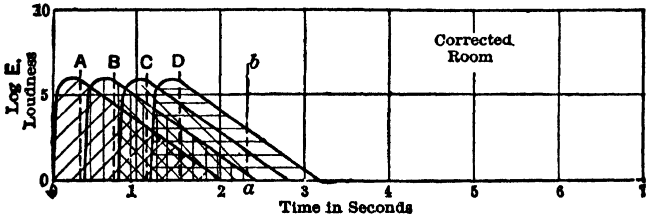

Fig. 9. Diagram Showing Beneficial Reduction of Overlap in Speech Sounds in a Corrected Room

Correction of Reverberant Rooms. The problem of correcting a reverberant room involves a calculation of the volume and absorbing values which are substituted in an equation developed by Wallace C. Sabine:

$$t = 0.05\ V/as$$

in which t = time in seconds for a standard sound to die out;
0.05 = a constant for standard loudness;
V = volume of the room in cubic feet;
as = absorption of all the surfaces and objects in the room.

The factor as is found by adding the absorptions of the different surfaces in the room as indicated by the equation:

$$as = a_1s_1 + a_2s_2 + a_3s_3 + \ .$$

where the surfaces s_1, s_2, s_3, . . . and likewise the coefficients a_1, a_2, a_3, . . . refer to the different materials. When the absorption as becomes large so that the average coefficient a exceeds the value 0 25, it is replaced by the factor $-\log_e (1 - a)$ as required by Eyring's equation. This means that the desired time of reverberation may be brought about by using a smaller amount of absorbing material.

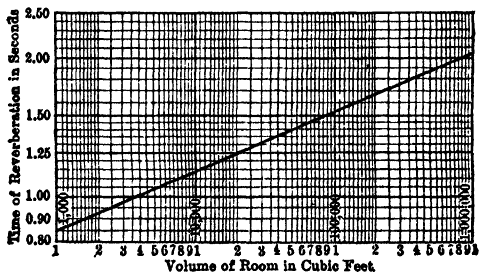

Fig. 10. Optimum Time of Reverberation for any Room

Optimum Time of Reverberation. A study of a large number of auditoriums gave data leading to the graph drawn in Fig. 10, which gives average values for the time of decay of a sound of the frequency 512 cycles per second for audi-

toriums of different volumes. It should be noted that the time in any auditorium should be short, not exceeding 2 seconds for a large volume of 1 000 000 cu ft.

Optimum Time of Reverberation for Different Types of Rooms *

Volume (cu ft)	Churches	Theaters and School auditoriums	Sound pictures
100 000 – 200 000	1.4 ±0.3 sec	1 2 ±0 3	1.2 ±0.2
200 000 – 400 000	1.6 ±0.3 sec	1.3 ±0.3	1.3 ±0.2
400 000 – 800 000	1 75 ±0.3 sec	1 4 ±0.3	1 4 ±0.2
800 000–1 000 000	1.85 ±0.3 sec	....	1.6 ±0 2

These values are for the frequency of 512 cycles per second, with capacity audiences present.

Table I.† Coefficients of Sound Absorption for the Average Pitch of 512 Vibrations per Second

Material	Coefficient per sq ft
Brick wall, painted	0 017
Brick wall, unpainted	0 03
Carpet, unlined	0 15–0.20
Carpet, felt-lined	0.20–0.35
Fabrics, hung straight:	
Light, 10 oz per sq yd	0.11
Medium, 14 oz per sq yd	0.13
Heavy, draped, 18 oz per sq yd	0.50
Openings:	
Stage, depending on furnishings	0 25–0 75
Deep balcony, upholstered seats	0 50–1 00
Grills, ventilating	0 15–0 50
Plaster, gypsum or lime, smooth finish on tile or brick	0 025
Plaster, gypsum or lime, smooth finish on lath	0 03–0.04
Plaster, gypsum or lime, rough finish on lath	0 06
Glass	0 03
Marble or glazed tile	0 01
Wood panelling	0.06
Floors:	
Concrete or terrazzo	0 015
Wood	0 03
Linoleum, asphalt, rubber, or cork tile on concrete	0.03–0.08
Seats and Audience	
Metal or wood chairs (units per seat)	0 17
Auditorium chair, wood veneer seat and back	0.25
Wood pews	0.4
Pew cushions	1.45–1.90
Theater chairs, upholstered in leatherette	1.6
Theater chairs, heavily upholstered, plush or mohair	2.6–3.00
Seated audience, per person (depending on character of seats)	3.0–4.3

* *Theory and Use of Architectural Acoustical Materials*, published by the Acoustical Materials Association, and republished with their permission.

† Copied from Bulletin II of the Acoustical Materials Association.

Absorbing Coefficients. Before installing absorbing materials to reduce the time of reverberation, it is necessary to know the absorbing value of various products that may be used in a room. A large number of these have been determined experimentally by Wallace Sabine and later investigators as shown in Table I. A perfect absorber is one that absorbs all the sound falling on it, so that its coefficient is 1. A material with the coefficient 0.50 will absorb half the sound incident upon it, or 50%.

Inspection of Table I shows that plaster, brick, wood and glass—the materials most commonly used for the interior surfaces of rooms—have small absorbing values, and account for the defective reverberation so prevalent in modern buildings. Porous materials such as hairfelt, carpets, fiber boards, cork, etc., as well as certain porous acoustic plasters, are usually good absorbers. The sound energy is converted into heat by friction in the pores of materials. An audience is a good absorber of sound on account of the clothing worn, and must always be considered in the acoustic correction of rooms.

Numerical Example of Acoustic Adjustment of a Room. Consider a room of 44 000 cu ft volume, for which optimum acoustics are desired when an average audience of 100 people is present. The optimum time of reverberation for a volume of 44 000 cu ft (Fig. 10) is 1.37 seconds, so that the absorption a needed according to Sabine's equation is:

$$1\ 37 = 05 \times 44\,000/a$$

from which, a = 1 610 units. The absorption of the room is as follows:

Open windows	30 sq ft at 1 00 =	30 units
Plaster on tile walls	6 000 sq ft at 0 025 =	150 units
Plaster on lath	3 000 sq ft at 0.033 =	99 units
Wood floor (varnished)	3 000 sq ft at 0.03 =	90 units
Seats 300	at 0.15 =	45 units
Total empty room		414 units
One-third audience, 100 at (4.7–0.15) *		455 units
		869 units

* An auditor adds only the difference between his absorption, 4.7 units, and the seat he covers, 0.15 unit, which has already been counted.

The room thus has 870 units, in round numbers, and will be too reverberant. It will be necessary to add 740 units of absorption to give the 1 610 units desired for optimum acoustics. The acoustic adjustment may be made in several ways, depending on the circumstances.

Solution 1. Install 1 580 sq ft of material at 0.5 = 740 units. This could be applied in decorative panels on the ceiling.

Solution 2. Install 3 700 sq ft of acoustic plaster at 0.2 = 740 units. Plastering the ceiling and the upper side walls would give the desired absorption.

Solution 3. Install 300 upholstered seats at 2.5 = 750 units.

Solution 4. (*a*) 300 upholstered seats at 1.6 = 480
(*b*) 1300 sq ft acoustic plaster at .2 = 260
— 740 units.

It is usually better to spread the absorption over some area, rather than concentrate a highly absorbent material on a small area. Upholstered sets make a room less dependent on the audience; if an upholstered seat is unoc-

cupied, it presents considerable absorption; if it is occupied the auditor adds the absorption of his clothing.

Selection of Absorbing Materials. When selecting a material for the acoustic adjustment of a room, several considerations should be held in mind.

(1) **The Absorbing Value of the Material.** To be effective, the material should be porous, preferably with rather large openings at the surface that allow sound to penetrate to the interior, where absorption takes place in the fine pores by reason of friction between the vibrating air particles and the walls of the pores. The absorption depends on the pitch of the sound, being a maximum usually for 1 000 to 2 000 vibrations per second. In computing the acoustic correction of rooms, the coefficients for the pitch 512 are used, as shown in Table I, since this value is found to be a satisfactory average of the coefficients for all the pitches. When comparing the cost of different materials, the absorption coefficient should be considered For example, 1 000 sq ft of a material of coefficient 0.5 gives 500 units of absorption ($1\ 000 \times 0.5 = 500$), while a material of 0.25 coefficient would require 2 000 sq ft to give the same number of units ($2\ 000 \times 0.25 = 500$).

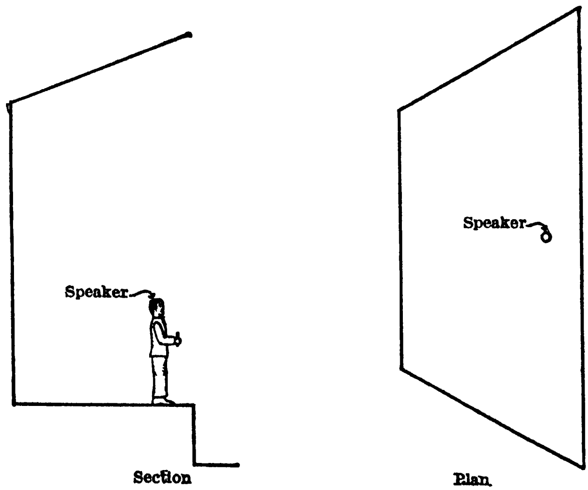

Fig. 11. Plan and Section of Reflecting Walls about Speaker or Musician to Give Perfect Generation of Sound

(2) **Painting or Redecorating Materials.** It is necessary to keep the pores of the material open if it is to retain its acoustic value. Materials with large channels or perforations can be painted without acoustic loss if these holes are not closed. Otherwise it is necessary to use special sprays in decoration.

(3) **Standard Materials.** Materials made at a factory and shipped for installation are more likely to have standard values than those made up on the job, where the skill of the workmen determines the efficiency.

Ideal Auditorium Acoustics. There is a need and desire for perfect acoustics in auditoriums, but the construction of such rooms is not common

because of lack of the necessary guidance. It has already been shown that the reflection of sound to auditors in auditoriums is responsible for most of the acoustic defects. The radical question then arises, is it possible to get rid of the reflected sound? The answer is, yes, as illustrated by an open-air theater; and these theaters always have good acoustics. The problem then is to make the indoor theater as dead as outdoors by the installation of sound-absorbing materials on the walls and ceilings, with upholstered seats on the floor. But will this not make the room too dead? No, provided certain reflecting walls are provided for the performers. Recent experiments show that speakers and musicians find it easy to talk or sing if they can "hear themselves" by the sound reflected from nearby walls. These walls should be as substantial as possible (but heavy painted canvas surfaces can be used) and should preferably not be more than 25 ft distant from the performer. Fig. 11 gives the plan and section of a suggested simple stage for satisfactory generation of sound by a performer.

There are two requirements for an ideal auditorium:

(1) For perfect GENERATION of sound, the performer should have reflecting walls near by to amplify the sound and allow him to "hear himself." Additional loudness, if necessary, can be obtained by the usual electric loud-speaker amplification.

(2) For perfect RECEPTION of sound by listeners, the reflection by walls and ceiling of a room should be reduced to a minimum by the use of sound-absorbing materials, so that the auditorium will be like an outdoor theater.

2. Soundproofing in Buildings

Need for Soundproofing. The problem of soundproofing in buildings has received an increasing amount of attention in recent years, because of the insistence on the reduction of noise. The demand for quiet rooms in hospitals, hotels, and office-buildings, the desirability of insulating music studios and rooms where disturbing sounds are produced, and the necessity for solving other problems for the control of noise have led to repeated inquiries by architects and builders for reliable information about effective methods of insulating sound.

Sound Insulation a Matter of Uncertainty. A number of perplexing problems are involved in the practical insulation of sound in buildings. The theory of the subject is incomplete, and practical attempts to secure effective soundproofing are not always attended with success, even though the constructions used are in accord with the theory and apparently have the elements of adequate insulation. Sound progresses with facility through the different solid materials in a building structure in paths not easy to trace, and may be heard in positions quite remote from the source. This action, together with the extreme sensitivity of the ear, explain why the insulation of sound is a difficult matter.

Two Types of Sound to be Considered. The general problem of soundproofing involves a consideration of two types of sound. First, there are those, such as violin sounds, that are generated in the air and progress in the air. These are quite effectively stopped by fairly rigid walls that do not have openings for pipes or ventilators. Second, there are vibrations, set up by an unbalanced motor that is rigidly attached to the building structure, that are very difficult to stop, and special devices are required to insulate the motor from the structure.

When sound is incident upon a partition, it is reflected, absorbed and trans-

mitted, the exact amount of each depending on the character of the partition and the incident sound. Fig. 12 pictures these effects.

Transmission of Sound Through a Partition. The sound emitted from the source S fills the room quickly where part of it is absorbed by the walls and part is transmitted into the second room. The transmission through the dividing partition can take place in three ways.

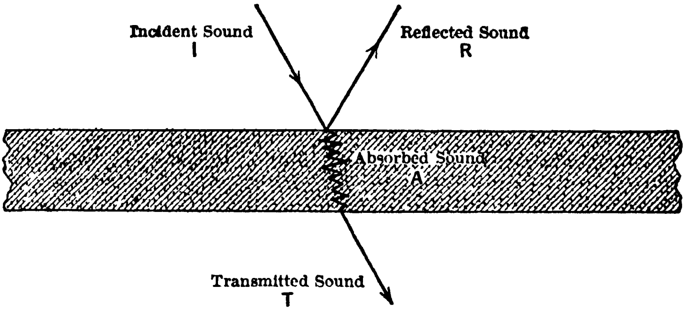

Fig. 12. The Reflection, Absorption and Transmission of Sound by a Partition

(1) It can pass easily through ventilating ducts, through cracks around doors or through other similar openings. Unless these air passages are stopped or guarded in some way, it is useless to build any "sound-proof" construction.

(2) The partition is set into forced vibrations by the rapid pushes and pulls of the sound compressions and rarefactions, so that it sets up sound waves in

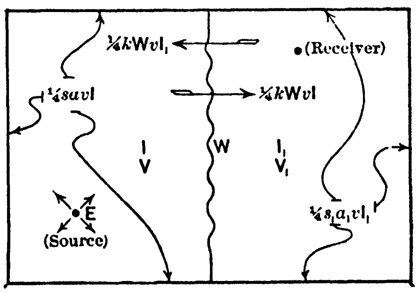

Fig. 13. Diagram Showing How Sound in One Room is Absorbed and Transmitted to Another

the room opposite the source. These vibrations, while very small, averaging about $\frac{1}{2500}$ in in amplitude, are yet sufficient to create audible sounds. It should be remembered that a vibratory motion of air particles of about $\frac{1}{250}$ in corresponds to the passage of a loud sound.

(3) Sound waves can go directly through the partition as an elastic-wave motion in which the pressures and rarefactions are transmitted from particle to particle in the partition and are communicated to the air on the farther

side. But the amount of sound thus transmitted through plaster partitions is very small, since more than 95% of the incident sound is reflected, and only a small fraction remains for possible transmission.

Experience shows that the transmission of sound is greatest through air passages; next in importance comes the vibration of the partition, while least of all is the transmission by elastic waves in the solid material in the partition. A continuous partition, with no cracks or openings, that is heavy and stiff, offers the best possibility of stopping sound. In building-constructions, however, it is desired that partitions be light in weight, easily constructed and cheap; so that the question arises as to how far one can depart from heavy, stiff constructions, and still get adequate soundproofing.

Musical sounds are more difficult to insulate than speech sounds. The tones of music are usually prolonged somewhat, which gives time to set up vibrations of walls and floors. Radio music has introduced a difficult problem of sound insulation in modern dwellings. If neighboring apartments are to be free from disturbing sounds, either the radio must be operated softly, or else the floors and walls must be made more robust.

Loudness of Sounds. To understand the experimental values obtained for different types of partitions, it is first desirable to explain the LOUDNESS of sound as perceived by people The ear is very sensitive to faint sounds, but is equipped with a protective mechanism that makes it more and more insensitive as the sound gets louder. In other words, the ear responds to the logarithm of the intensity rather than the intensity. For example while 100 violins would be 10 times as INTENSE as 10 violins, they would sound only twice as LOUD ($\log 100 = 2$, $\log 10 = 1$).

The loudness values are expressed by acoustical engineers as DECIBELS (abbreviated to db), which are obtained by multiplying the logarithm of the intensity by 10. Thus a standard sound, 1 000 000 times as intense as a sound barely audible, would have a loudness of 60 decibels ($10 \times \log 1\,000\,000 = 60$ db).

A scale of loudness is shown in Fig. 13, which gives the values of some usual sounds in terms of decibels. The zero of this scale is the loudness of sound that is barely perceptible; ordinary conversation between persons about 3 ft distance from each other varies from 35 to 65 db, an airplane has the loud sound of about 95 db, while a sound of 108 db is the loudest that the ear can stand without pain. This scale is based on an average complex sound given by the Western Electric 3A audiometer. For sounds of very low or very high pitch, the scale would not be applicable

Experiments on Transmission of Sound through Partitions. Experimentally, in determining the transmission efficiency, the procedure is to measure the intensity I' of the incident sound in front of the partition and also the intensity I'' on the farther side after the sound is transmitted. Results are expressed either as the REDUCTION FACTOR, I'/I'', or as the logarithm of I'/I''. To be effective, a partition should reduce the intensity at least 1 000 fold, so that an incident sound of intensity $I' = 1\,000\,000$ should be reduced to $I'' = 1\,000$, after transmission. The logarithm I'/I'' is thus 3, or 30 decibels reduction. Referring to Fig. 14, this would mean that a sound of 60 decibels would be reduced to 30 db, or 50 decibels to 20, etc.

Transmission of Sound by Floors. It appears that sound is more easily transferred through floors than through partitions. This is due to actual contact of sound-producing bodies with the floor, such as pianos, radios, persons walking, etc. Tapping a wall or floor with a solid object will produce a sound that is easily heard in the room below, while talking or clapping one's

hands generates a sound in air that has greater difficulty in penetrating the wall or floor. For this reason, it is desirable that the floor be made of more robust construction than walls, and fortunately this is usually the case, because the floor must be built strong enough to carry the weight put upon it.

In this connection, it is interesting to note that in buildings constructed of concrete and masonry, the floors are strong and heavy, while the partitions which are carried by the floors are as light in weight as possible. For this reason, the problem of soundproofing in such a building is more concerned

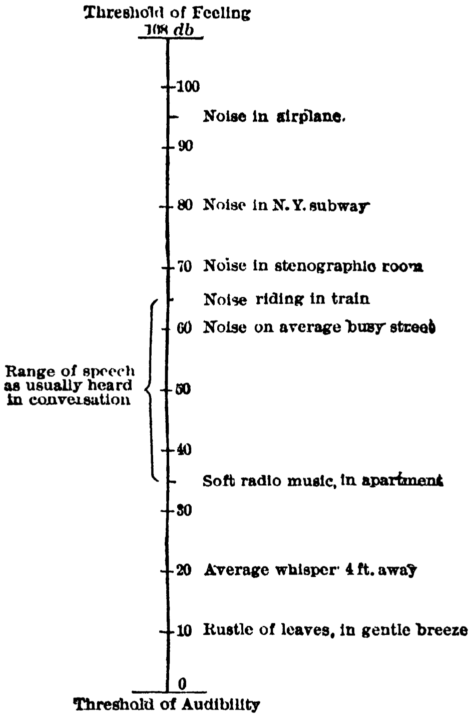

Fig. 14. A Scale of Loudness (Waterfall)

with the partitions than with the floor. With buildings constructed of wood the opposite is true, for in this case the partitions carry the floors, and there is more trouble with transmission through floors than through partitions.

Numerical Example of Transmission of Sound. The effectiveness of a partition in reducing sound may be expressed in terms of the loudness scale. Suppose that conversation of 60 db loudness takes place in a room. The absorption of the walls and furnishings may reduce this 5 db to 55 db. In passing through an effective partition, the loudness may be reduced, say, 30 db, to the value 25 db. The absorption of the second room will further

reduce the sound 5 db to a final value of 20 db, which is so weak that it is scarcely noticed. If, however, the original sound was due to a loud radio of say 80 db, the reduction by the rooms and the partition would be the same number of db as before $(5 + 30 + 5 = 40)$, but the residual loudness would now be 40 db, which would be objectionable.

The quieting effect of materials on the walls of a room is given in an interesting experiment by Chrisler.* "A practical demonstration of the above statement was made by lining a large box with highly absorbing material. The average reduction factor of this box was slightly under 40 sensation units. The box was placed in a very reverberant room. A person inside the box could understand everything said by a person outside, while the person outside was unable to understand a single word that was spoken by the person inside unless he raised his voice. The reason for this was that the absorbing material in the box lowered the intensity of sound originating within to such an extent that it was no longer sufficient to carry through and be audible after transmission."

This example shows that the reduction of sound depends on the absorption of the walls, as well as on the effectiveness of the partition. Davis † has given a formula: $I''/I' = \dfrac{kW}{a_1s_1}$ where k is the transmission per sq ft of the partition; W, the area of the partition; and a_1s_1, the absorption of the room into which the sound is transmitted. Numerical data obtained by different laboratories for I'/I'' for the same type of partition do not agree, probably because the areas of the partitions and the absorption of the receiving-rooms are different. The value of k, however, should have the same value for any condition of test.

Experimental Values of Sound Reduction by Partitions. A great amount of data on sound reduction by partitions has been obtained in different laboratories, but the values of log I'/I'' do not always agree, as just explained. For example, in the following results for wood-stud partitions, the values obtained by the Bureau of Standards with a reverberant receiving-room are about double the Riverbank values where the receiving-room was quite dead acoustically.

Table II. Reduction of Sound by Wood-Stud Partitions *

Lath	Plaster	Coats	Lb per sq ft	10 × log reduction factor	
				Riverbank	Bur. standards
Metal	Gypsum	S & B	17 4	27 0	53 7
Wood	Gypsum	S & B	18.0	27 3	46 9
Wood	Gypsum	S, B, F	18.6	28 0	42 7
Wood	Lime	S, B	17.4	35.4	69.1
Wood	Lime	S, B, F	18.0	35.2	60.8

* P. E. Sabine, Amer. Arch't., August 5, 1926.

Riverbank values are averages for 17 tones from 128 to 4 096 vibrations

* Bureau of Standards, Research Paper No. 48.

† Philosophical Magazine, Vol. 50, page 75, 1925; Vol 2, page 543, 1926

per second. Bureau of Standards values are averages for four frequency bands, 250 to 3 470 vibrations per second.

Some conclusions drawn (P. E. Sabine) are:

There is no important difference in the sound insulation afforded by gypsum plaster laid on metal lath and the same material laid on wood lath;

Compared with similar tests on masonry partitions, the wood-stud construction gives the same sound reduction as an all-masonry wall of equal weight;

Oral tests showed that speech of conversational loudness could be heard and understood easily through all these partitions.

Sound transmission measurements were taken by Wallace Waterfall * on actual partitions in apartments, as well as on the same types of construction in the laboratory. Measurements were taken by the ear and also by instruments. The following table gives one set of results obtained for wood-stud partitions showing the relative values obtained by three methods: reverberation (ear), audiometric (ear), and instrumental.

Reduction of Sound by Wood-Stud Partitions (Waterfall)

Method	Pitch of sound				
	256	512	1024	2048	Average
Reverberation (P. E Sabine)	22 6	34	40 8	36 6	33 5
Audiometric (ear)	29	34	37	42	36
Instrumental *	29	30	36	43	35

* In this method, the sound was "wavered" on either side of the pitch indicated. The agreement of the average values is gratifying.

The following table † gives data on plaster partitions, for range of pitch 128 to 4 096 vibrations per second. The partitions were 8 ft 2 in by 6 ft 2 in

Table III. Sound Reduction for Plaster Partitions (P. E. Sabine)

Partition	Lb per sq ft	10 × Av. log I′/I″
2-in Gypsum tile, unplastered	10 4	23 6
3-in Hollow tile, unplastered	11 1	24 2
1½-in Plaster on metal lath	13 9	25 3
3-in Solid gypsum tile, unplastered	14 2	26.7
2-in Solid gypsum and 1½-in plaster	15 0	27 2
4-in Hollow clay tile, unplastered	17 0	28 3
2-in Gypsum and 1-in plaster	19 6	29 5
2-in Gypsum and 1¼-in plaster	21 4	30 5
4-in Clay tile and ½-in plaster	22 0	30.7
2½-in Plaster on metal lath	23 2	32 4
3-in Solid gypsum and 1¼-in plaster	25 4	32 8
4-in Hollow clay tile and 1-in plaster	27 0	33 6
4-in Hollow clay tile and 1¼-in plaster	28 8	34 0
3½-in Plaster on metal lath	32.5	36.0
4½-in Plaster on metal lath	41.8	38.2

† P. E. Sabine. Amer. Arch't, July 4, 1923.

in area, built in between two entirely separate rooms. It is to be noted that the reduction of sound (10 log I'/I'') is proportional to the weight of the partition per sq ft, the heavier partitions thus stopping more sound.

Experimental Work at Bureau of Standards. The transmission of sound through a large number of structures has been measured.* The lightest material tested was wrapping paper, while the heaviest structure was a combination tile floor with a cinder fill and concrete finish, weighing 109 lb to the square foot. For structures that are approximately homogeneous, such as masonry partitions the log I'/I'' is proportional to the logarithm of the weight per unit area. This conclusion, which was also found by P. E. Sabine, means that the sound reduction is more effective with the heavier partitions.

The following table gives some of the results obtained in the investigation just mentioned. (Original paper should be consulted for details.)

Table IV. Sound Reduction by Walls and Floors
(Chrisler & Snyder)

Material	Lb per sq ft	10 × Av. log I'/I''
Hollow clay tile, 3 in thick, plastered both sides	28	44 4
Hollow clay tile, 4 in thick, plastered both sides	29	43 5
Hollow clay tile, 6 in thick, plastered both sides	37	44.6
Hollow clay tile, 8 in thick, plastered both sides	48	49.8
Hollow clay tile, double 3 in partition, 1¾ in air space containing 1 in Flaxlinum.	50	59.2
Brick panel, 8 in thick, plastered both sides .	97	56 7
Single sheet of galvanized iron, 0 03 in thick	1.2	28 3
Single sheet plate glass, ¼ in thick	3.5	32.7

Practical Results Obtained by Various Partitions. As already explained, the numerical results for log I'/I'' obtained by different laboratories do not agree. Some comparison of results is obtained by the following explanations.

At the Bureau of Standards, the data are classified in four groups, as follows:

"**Panels Whose Reduction Factors are Over 60 Sensation Units.** Conversation carried on in an ordinary tone of voice is reduced to inaudibility. If there is external noise in the listening-room, a shout on the other side of the panel would be practically unnoticeable.

"**Panels Whose Reduction Factors Lie between 50 and 60 Sensation Units.** Conversation in ordinary tones heard through the panel is barely audible but unintelligible.

"**Panels Whose Reduction Factors Lie between 40 and 50 Sensation Units.** Conversation in ordinary tones heard through the panel is quite audible but difficult to understand. If the voice is raised, it becomes intelligible.

"**Panels Whose Reduction Factors Are Less Than 40 Sensation Units.** Conversation in ordinary tones heard through the panel is distinctly audible and intelligible."

At Riverbank Laboratories, P. E. Sabine states (see Table III) "speech of conversational loudness could be heard and understood easily through all these partitions." The partitions were wood-stud with sound reduction of 27 to 35 sensation units (decibels).

* V. L. Chrisler and W. F. Snyder. Research Paper No. 48.

Waterfall * gives the following observations:

"With an average reduction factor of 25 db, normal speech can be understood quite easily and distinctly through the partition.

"With an average reduction factor of 30 db, loud speech can be understood fairly well if conditions are quiet.

"With an average reduction factor of 35 db, loud speech is audible, but not easily intelligible under quiet conditions.

"With an average reduction factor of 40 db normal speech is not audible, loud speech can be faintly heard, but not easily understood, and for all practical purposes the partition can be considered as 'sound proof.' Separating partitions between apartments should have a factor of about 40.

"For piano-rooms, organ-rooms, etc., a better partition is sometimes needed. Higher factors than 40 are desirable for such cases."

Acoustic Control of Ventilation System. One of the greatest sources of acoustic trouble in buildings is the ventilating system. Sound travels easily from room to room through these "speaking tubes." An effective means of reducing this transfer of sound is to use small, individual pipes that extend from the supply chamber to each room without the usual large main duct. Large pipes can be padded on the inside to reduce sound. Baffles of sound-absorbing material help. A mushroom cap over open ends of pipes in attics has proved beneficial. Low-velocity fans, with balanced motors, create less disturbing noises than small high-velocity machines.

Vibrations in Buildings. Vibrations may be set up in the building itself by motors, elevators, etc., or they may be originated outside by street-cars, trucks, and trains. Such vibrations are likely to disturb occupants in buildings because of mechanical vibration of the floors, or by the annoying sounds set up by vibrating partitions, by rattling windows and other loose constructions.

These vibrations will be minimized in buildings that are massive in construction. It is helpful to have balanced motors and other quiet-running machinery. Padding placed under machines is helpful, but the vibrations are complex so that successful results are not always obtained.

CHAPTER XXXVI

ARCHITECTURAL SHADES AND SHADOWS

By
GEORGE W. BAUMEISTER
ASSISTANT PROFESSOR OF GRAPHICS, SCHOOL OF FINE ARTS,
UNIVERSITY OF PENNSYLVANIA

1. Relation to Architectural Drafting

Relation to Architectural Drafting. The science of all drafting is called DESCRIPTIVE GEOMETRY. It has sometimes been called the grammatical construction of the language of graphics. All the real progress in the growth of that language began with the formulation of this science about the beginning of the nineteenth century. The function of descriptive geometry, as its name implies, is to describe (in the language of graphics) geometric forms in space. Applied to architecture, its general function is to describe, upon a plane surface, the three dimensions of buildings, their details and entourages. In this application it is called ARCHITECTURAL DRAFTING.

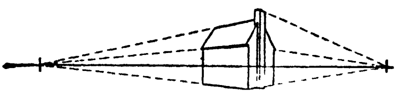

Fig. 1. A Perspective Drawing

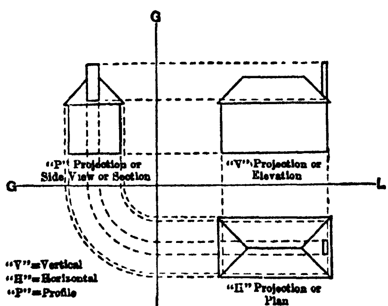

Fig. 2. Ortho-graphic Projection

Architectural Drafting. To accomplish its purpose, ARCHITECTURAL DRAFTING resorts to either of two conventions, called PROJECTIONS, wherein, imaginary projecting lines, called VISUAL RAYS, are conceived as drawn from the lines of the object in space to imaginary receiving planes, and the resulting image is drawn on paper.

These two systems of projections, employed in architectural drafting, are in their chronological order:

(1) CONIC PROJECTION, or PERSPECTIVE DRAWING (Fig. 1). (Isometric, oblique and cabinet drawing, etc., are modifications of perspective drawing which find but little use in architectural drafting.)

(2) ORTHO-GRAPHIC PROJECTION, commonly called MECHANICAL DRAWING (Fig. 2).

A brief description of these two systems will help to explain the statement of the function and importance of each. They differ only in the assumed location of the observer's eye, from which point the imaginary projecting lines, or visual rays, are conceived to be drawn.

Conic projection or perspective drawing, although conventional drafting, makes some concessions to the natural laws of vision. The IMAGE-RECEIVING PLANE is conceived to be a single plane (the picture plane), and the observer's eye to be located at a reasonable finite distance (Fig. 3). The projecting lines (or visual rays) then converge to a point (the observer's eye). When the resulting picture plane projection is drawn, it is called a perspective drawing (Fig. 1). Man's very first attempts to draw were efforts at natural representation, i.e., perspective drawing.

Ortho-graphic projection, on the other hand, is the extreme of conventional drafting. The interesting thing is, that perspective should have developed so far before this system originated. In this system the image-receiving planes are conceived to be the three planes of projection, called the coordinate planes, VERTICAL, HORIZONTAL and PROFILE, in a tri-rectangular relation, and the observer's eye to be located at an infinite distance. The projecting lines, or visual rays, to each coordinate plane, are parallel to each other and

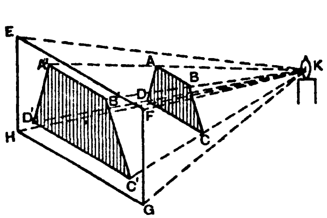

Fig. 3. Perspective or Conic Projection

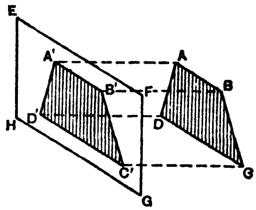

Fig. 4. Ortho-graphic Projection

perpendicular to their particular plane of projection (Fig. 4). When the resulting vertical or V, horizontal or H, and profile or P projections are drawn upon a plane surface, they are called, respectively, ELEVATION, PLAN, and SIDE-VIEW or SECTION (Fig. 2). The terms V projection and elevation, H projection and plan, P projection and side view, are therefore used interchangeably.

Working Drawings and Rendered Drawings. Generally speaking, in the architectural drafting of today, these plans, elevations and perspectives may be divided into WORKING DRAWINGS and RENDERED DRAWINGS.

Working drawings can be dismissed from our consideration here, for no matter how intricate the working drawing may become, it has but one supreme function, that is, to convey information. It must always remain the extreme of careful, conventional drafting for two reasons: (1) to eliminate the least possibility of misinterpretation, and (2) to have the effect of inspiring neat and careful results in work done under its guidance.

Rendered drawings, on the contrary, are intended to convey both information and an impression, and may vary, according to their exact purpose, all the way from simple washes applied to conventional plans and elevations, to the less conventional but more elaborate presentation of a rendered perspective. Indeed, because linear perspective is already a concession to the natural laws of vision, its rendering, in its tendency toward natural representation, may very easily overstep the bounds of conventional architectural drawing. It then becomes a picture instead of a drawing, for its main purpose is to convey an impression rather than to convey information. Aside from the technique, the difference between painting a picture and making a drawing is extremely fundamental. In painting a picture the artist hopes to express

and convey a definite mood, such as awe inspired by the grandeur and majesty of a storm, or serenity created by the peace and beauty of a rural scene. In his picture he is not so much concerned with the outline of a wave or of a tree, or even with the reproduction of what are regarded as exact natural colors. But he is interested with imparting to the beholder the mood which has been created within himself. The degree of success which he attains in this purpose is alone the measure of the artist's ability. A draftsman may be skilled in the technique of pencil and brush and yet lack this final requirement to be an artist.

The Function of Shades and Shadows in Rendered Drawings. However, regardless of how much rendering is applied to architectural plans and elevations to express plane values, textures, colors, etc., they must remain, in their nature, descriptive, conventional drawings conveying accurate information. That is, they must remain the linear drawings of either ortho-graphic or perspective projection, and when, for instance (Fig. 5), in rendering the elevation of a building, the projections of the shade and shadow surfaces of the various architectural features are added, their purpose is not primarily to make a picture, but to express the facade's third dimension. If these shade and shadow surfaces are to fulfil this primary purpose, their outlines must be obtained according to certain fixed rules and conventions, so that their graphic language may also have constant significance and be universally understood. These fixed rules and conventions constitute the SCIENCE OF SHADES AND SHADOWS.

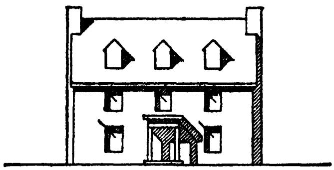

Fig. 5. An Elevation

2. Character and Scope

Character and Scope. The science of shades and shadows, as employed by geometricians, may be said to have two principal purposes: (1) to furnish exercise in developing the mental ability to completely visualize and realize geometric description (sizes, shapes and relative positions) of geometric surfaces in space; (2) to express this mental concept in graphics, by devising means of determining, both accurately and quickly, the outlines of the conventional light, shade and shadow parts of surfaces.

This abstract study of the theory of the science of shades and shadows, as an application of descriptive geometry, is admittedly of greatest fundamental importance to the architectural student, as elementary training in the creative processes of the mind. To be of practical value to him, however, the concrete result of such a study must be the acquisition of a vocabulary of projections of shade lines and shadow lines of constantly recurring architectural forms. Complete understanding of the derivation of this vocabulary assures its intelligent use, and both the rendering and the reading of architectural plans and elevations are greatly facilitated. The development of this vocabulary is really the distinguishing characteristic of that application of the science of shades and shadows which is called ARCHITECTURAL shades and shadows.

The Art of Rendering Architectural Shades and Shadows. In conventional architectural drafting the SCIENCE OF DETERMINING architectural shades and shadows is so closely associated with the ART OF RENDERING architectural shades and shadows that they are very frequently confused. At this point therefore, it is important that their fundamental difference be clearly under-

stood. The division, by lines, of all surfaces into their light, shade and shadow parts, according to certain conventions, is a matter of mathematical precision. The science, the function of which is to devise the processes for determining these lines is called the SCIENCE of shades and shadows. It is an application of descriptive geometry. The realistic modeling of these separate light, shade and shadow parts of surfaces (with their outlines thus carefully determined) to resemble natural light effects is a function of the ART of architectural rendering. No matter how realistic this rendering may become, the original lines of demarcation between the light, shade and shadow parts must be maintained as long as the subject is a conventional drawing and not a picture.

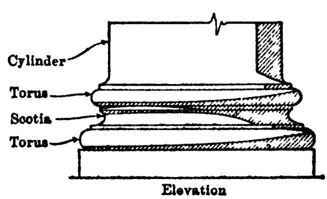

Fig. 9. Attic Base

Natural Shades and Shadows. In nature, a surface becomes visible only when rays of light reflect from it to an observer's eye. Thus it is reflected light which reveals the sizes, shapes and locations of surfaces in space. Hence, any surface exposed to light immediately becomes another source of light.

This reflected light, although less intense than the original direct light (on account of the absorption and refraction of some rays for color, etc.), is misleading and tends to render the perception of the true sizes, shapes and relative positions of adjacent surfaces difficult and sometimes even impossible. Surfaces, IN NATURE, are classified as (1) HIGH LIGHTS, (2) LIGHTS, (3) SHADES and (4) SHADOWS, with all the intermediate gradations which only the human visual mechanism can detect and register. In an effort to express in drawings only the true size and relative positions of adjacent surfaces, and that as emphatically as possible, CONVENTIONAL shades and shadows are employed.

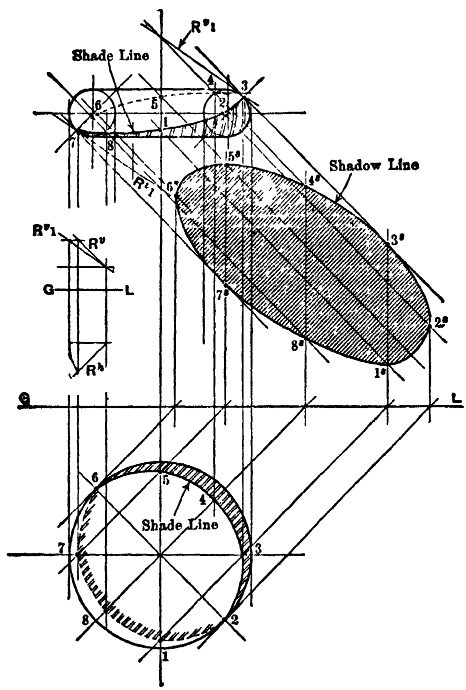

Fig. 9A. Shade Line and Shadow Line of a Torus

Conventional Shades and Shadows. The shades and shadows which are supposed to result when objects are conceived as being exposed to an assumed direct light, which is in a certain fixed position, are called CONVENTIONAL shades and shadows. The amount and direction of the light are then assumed to be constant. The light in conventional shades and shadows is assumed to have but one direct source, i.e., the sun, located at infinite distance, so that the rays may be taken as parallel to each other. It is assumed to be of constant intensity and location, and arbitrarily divides all surfaces, regardless of their geometrical description, into light, shade or shadow surfaces, recognizing no intermediate gradations.

Light, Shade and Shadow Surfaces. Light, shade and shadow being attributes of geometric surfaces when exposed to light, an understanding of the fundamental principles of geometry is essential. It must be remembered at the outset that the points, lines, surfaces and solids of plane and solid geometry are purely ideal. A solid in common language is something real, i.e., a limited portion of space filled with matter; but a geometrical solid is purely an ideal, i.e., a limited portion of space which may be occupied by a physical body, or marked out in some other way. The surface of a solid is simply the boundary of the solid, i.e., that which separates it from surrounding space. The surface is no part of a solid, and has but two dimensions, length and breadth, but no thickness.

Although the general science of shades and shadows considers every conceivable solid of pure geometry, its limited application to architecture must of necessity be restricted to consideration of the simple geometric solids which represent an analysis of architectural detail.

Tabulation. The geometrical forms to which constantly recurring architectural detail (both casting and receiving shadows) can be reduced, by convention, are tabulated in the table and illuminated in Figs. 6, 7, 7A, 8, 9, 9A, 10, 10A, 10B, 10C, 10D, and 11.

	Kind of solid	Kind of surface	Examples of occurrence in architecture
1	Prism	Plane	Plane wall buildings (Fig 6)
2	Pyramid	Plane	Plane roofs (Fig 6)
3	Convex right circular cylinder	Convex single curved	Column shafts, towers, moldings etc. (Figs 7, 7A and 9)
4	Convex right circular cone	Convex single curved	Conical roofs (Fig. 7)
5	Sphere	Convex double curved	Domes, balls, etc. (Fig 8)
6	Torus	Convex double curved	Moldings such as column bases (Figs. 9 and 9A)
7	Hollow right circular cylinder	Concave single curved	Niches, moldings, etc. (Figs. 10 and 10A)
8	Hollow right circular cone	Concave single curved	Moldings and ornament (Fig. 11)
9	Hollow hemisphere	Concave double curved	Moldings and ornament (Figs 10 and 10B)
	Hollow scotia	Concave double curved	Moldings and ornament (Fig, 10D)
	Hollow torus	Concave double curved	Moldings and ornament (Fig. 10C)
	Scotia	Concave double curved	Moldings such as column bases (Fig. 9)

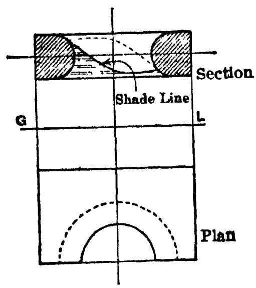

Fig. 10D. Hollow Scotia or Gorge

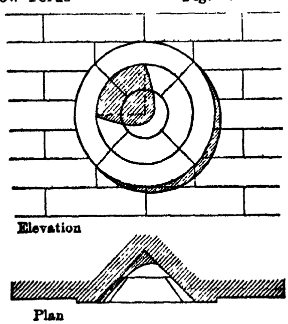

Fig. 11. Hollow Cone

3. Conventions

Conventions. It has been shown that the science of shades and shadows ignores completely the geometrical classifications of surfaces and recognizes but three classes of surfaces: (1) light, (2) shade and (3) shadow (Fig. 14).

In the study of light, shade and shadow surfaces, with reference to their cause, the one outstanding fact of importance to remember is that LIGHT MUST TRAVEL IN A STRAIGHT LINE. Then, however light or dark a surface may appear depends upon its inclination toward the light, and reveals its size and shape. Its position relative to other surfaces is disclosed by the shadows which it receives and casts. Shadows in nature contribute to revealing size, shape and position not only of the objects casting the shadows, but also of the surfaces receiving the shadows.

Source of Light. In its effort to express upon architectural drawings only the true sizes, shapes and relative positions of surfaces, and that as emphatically as possible, SHADES AND SHADOWS assumes but one source of direct light, i e , the sun. This avoids the confusion and difficulties encountered in natural vision caused by various other sources of light (reflected, diffused, or artificial).

Ray of Light. In its effort to standardize the projections of the outlines of the light, shade and shadow surfaces, and thus make their language universal, the convention of shades and shadows assigns a fixed location to the sun, so

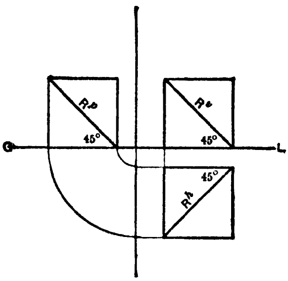

Fig. 12. Projections of the Conventional Ray of Light

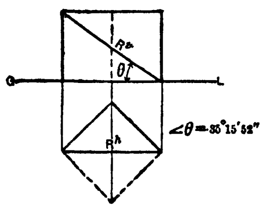

Fig. 13. True Angle of the Conventional Ray of Light

that the conventional rays of light, besides being assumed parallel to each other, arrive at the object in space from a constant direction and at a constant angle. The assumed direction and angle of the conventional ray of light have so many practical advantages that they are, with rare exceptions, universally accepted. In architectural shades and shadows they are practically invariable. It is universal to assume the rays of light of conventional shades and shadows as parallel lines coming over the left shoulder and sloping down toward the right with their projections making 45° with the *GL* (ground line), in other words, parallel to that diagonal of a cube which slopes *d–b–r*, i.e., downward, backward, to the right, when the cube has two faces parallel to each of the three coordinate planes (Fig. 12). The actual angle which the ray of light makes with any one coordinate plane is of course the angle of the diagonal of any cube with its base, 35° 15′ 52″ (Fig. 13). The practical advantage in drafting of having all three projections of the ray of light at 45° with the *GL* is self-evident. Other advantages will become immediately apparent in the later study of the shadows of certain straight lines and circles

4. Definitions and Principles

Definitions and Principles. Fig. 14 illustrates the principles and terms employed in ARCHITECTURAL shades and shadows. An object in space, such as a sphere, is conceived to be exposed only to the direct light of the sun which is assumed in CONVENTIONAL shades and shadows. It is said to cast a shadow upon the surface or part of the surface of a second object when the first object is so situated as to prevent light rays from reaching the surface of the second object The object excluding the light may be entirely external (as in this instance), or it may be an attached projection (as a pilaster or a cornice) (Fig. 15), but it received the light which the shadow surface otherwise would receive Depending upon its position relative to the assumed

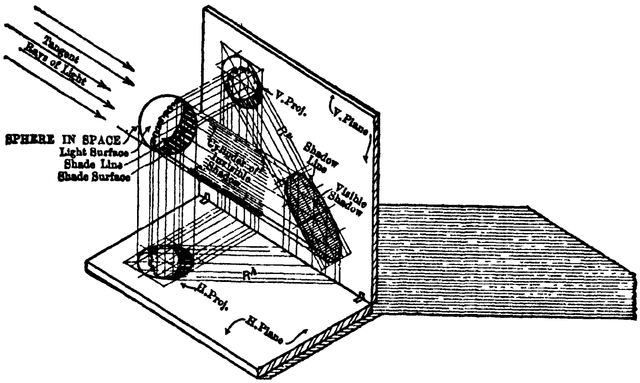

Fig. 14. Light, Shade and Shadow of a Sphere

light and adjacent surfaces, every surface is distinctly classified as light, shade or shadow.

(1) **A light surface** is that portion of the surface of a solid which, because of its shape and position, is reached by direct light (Fig. 14).

(2) **A shade surface** is that portion of the surface of a solid which, because of its shape and position, is not reached by direct light (Fig. 14).

(3) **A shadow surface** is that portion of the surface of a solid which, although faced directly toward the light, receives no direct light because of the intervention of some surface nearer the sun (Fig. 14). (A plane surface to which rays of light are exactly tangent is called a SURFACE OF LIGHT AND SHADE and is treated as a shade surface, the theory being that the first line of the surface is the only one in a position to receive direct light) (Fig. 16).

(4) **Shade Line.** The line dividing the light surface from the shade surface upon a plane or convex curved surface solid is called its SHADE LINE. Obviously it is formed by adjacent points of tangency of successive rays of light (Fig. 14). The shade line of a concave surface is called a FALSE SHADE LINE, because although it is formed by tangent rays of light it does not cast shadows. It divides shade from shadow (Fig. 17).

(5) **Invisible Shadow.** The rays of light coming from the sun are tangent to the object along its shade line. They continue on beyond the object, forming the surface of a geometric solid or INVISIBLE SHADOW (an absence of light in space) (Fig. 14).

(6) **Shadow Line and Visible Shadow.** When this geometric solid of invisible shadow with its surface composed of light rays, reaches the next

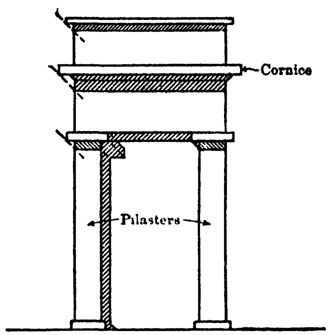

Fig. 15. Shadows Cast by Projecting Parts

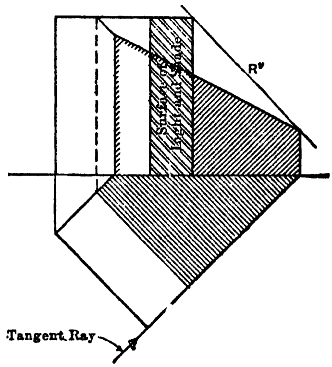

Fig. 16. A Surface of "Light and Shade"

material surface, the outline of their intersection is called the SHADOW LINE and the intersection is called a cast VISIBLE SHADOW (Fig. 14).

Distinction between Actual Shade and Shadow Lines in Space and Their Geometric Projections upon Architectural Drawings. Although we almost invariably, in practice, use the terms SHADE LINE and SHADOW LINE to describe them, actually, in theory, it is the geometric projection of the shade line or of the shadow line which is shown upon architectural plans and elevations. This is the same thing only when they lie in plane surfaces identical with the coordinate planes of projection. Otherwise it must be constantly remembered that, whereas the shade and shadow surfaces are actually part of objects in space, the shade and shadow lines are parts of the projected drawing. To illustrate, a shadow line may be an ellipse in space but a circle in projection (see Figs. 36 and 37), or it may be a broken line in space and projected as a straight line (Figs. 32–33–34–35). Similarly, a shade line may be a circle in space but an ellipse in projection (as the shade line of a sphere, Fig. 14). When the architectural drawings are geometrical plans and elevations, it is, of course, the geometric projections of the outlines of the light, shade and shadows surfaces which we want. When these surfaces, so outlined, are rendered, they express a third dimension upon an otherwise two-dimensional

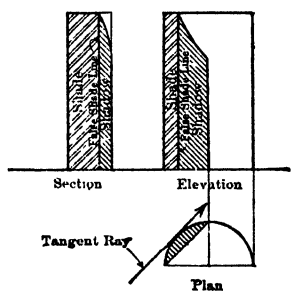

Fig. 17. "False" Shade Lines

drawing. Therefore, since the information which they convey is definite, it is extremely important that they be both accurately found, and clearly and accurately drawn. There can be no compromise; they must be correct. The correct outlines of the shade surfaces (in projection), and the correct outlines of the shadow surfaces (in projection), are just as vital to a rendered architectural drawing as the correct outlines of the geometric surfaces (in projection). They are, in fact, integral lines in the drawing. If the architectural drawing is a perspective, the shade lines and shadow lines are drawn in perspective just as any other line of the drawing.

Fundamental Principles. From the above explanations and definitions, and study of Fig. 14, it is extremely important to realize the following axioms. In casting shadows they should continually be borne in mind, as they are the very fundamental principles.

(1) The SHADE LINE is determined by tangent rays of light; and the SHADOW LINE is determined by incident rays of light.

(2) The SHADOW LINE of any object whatever upon any surface is the shadow of its SHADE LINE.

(3) SHADOWS always fall upon surfaces faced toward the sun, i e., light surfaces.

(4) Surfaces which are turned away from the sun are SHADE SURFACES and incapable of receiving shadow.

(5) Any surface or portion of a surface already in shade or shadow cannot cast shadow because of the absence of light.

(6) For any surface in light there is a shadow.

(7) The shape of the VISIBLE SHADOW which is cast by any object in space upon any surface depends upon three factors alone, as follows: (*a*) the shape of the surface of the object which is casting the shadow; (*b*) the shape of the surface of the object receiving the shadow; (*c*) the relation of both these surfaces to the direction of the assumed source of light.

5. Theory of Casting Shadows

Theory of Casting Shadows. In attempting to cast ARCHITECTURAL shades and shadows it must, above all, be clearly understood that the SHADOW LINE of any solid, whether its surface be plane or curved, is actually nothing more than the shadow of a certain line in that surface, i.e., its SHADE LINE (Fig. 14). Then it can readily be seen that the work of finding the shadow of any solid is equivalent to finding the shadow of a certain limited portion of its surface. The SHADOW LINE of a surface or part of a surface is obviously the shadow of its boundary line, but the shadow of any line is only the shadows of the points in that line. Therefore, in the final analysis, the important fundamental step to which all shadow-casting is finally reduced is FINDING THE SHADOWS OF POINTS. Equipped with the knowledge of how to find the shadow of any point upon any surface, one is prepared to cast the shadow of any line upon any surface, and finally therefore of any surface upon any other surface.

Methods of Casting Shadows. The shadow of a point upon any surface whatever is never anything but the point where a ray of light drawn through that point in space pierces the surface whereon the shadow falls (Fig. 18). There are but two methods of finding the shadows of points (and hence of lines and surfaces): first, the method of OBLIQUE PROJECTION and second, the SLICING method.

When the surface receiving the shadow is of such kind and position that it can be projected as line, i.e., plane or single curved and perpendicular to V, H or P, then the method is an elementary problem in descriptive geom-

etry. It is called the method of OBLIQUE PROJECTION, and it never varies. When, however, the plane or single curved surface receiving the shadow is oblique and cannot be projected as a line in V, H or P, or is a double curved surface which can never be projected as a line, then the SLICING method must be used.

To Find the Shadow of a Point by Oblique Projection. This method consists simply of passing an OBLIQUE line through the point, parallel to the conventional ray of light, and the point where this line strikes the intercepting

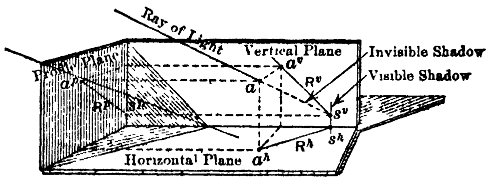

Fig. 18. The Shadow of a Point

or receiving surface is the visible shadow of the point (Fig. 18). The part of the line between the point in space and its visible shadow is called its invisible shadow. The line which is the projection of the shadow receiving surface becomes the GROUND LINE (GL) for the shadows.

Geometric Demonstration. Definition. The shadow of a point is the trace of a ray of light drawn through that point.

The simplest illustration of this method of finding the shadow of any point upon any surface is found in the shadow of a given point upon either the

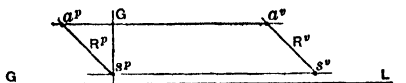

Fig. 19 Using the "P" and "V" Projections

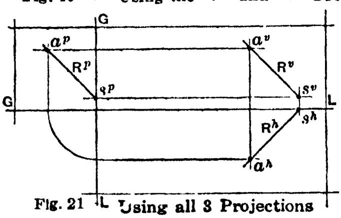

Fig. 21 Using all 3 Projections

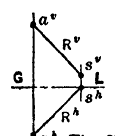

Fig. 20 Using the "H" and "V" Projections

Figs. 19, 20, 21. The Shadow of a Point by "Oblique Projections"

V or H coordinate planes, while using these two projections to obtain the shadow.

Assume a point a, located by its projections, a^h and a^v and a^p to be 1 in from V and $1\frac{1}{2}$ in from H.

Being nearer to V than H, its shadow will fall upon the vertical coordinate, and either the P and V (Fig. 19), or H and V projections (Fig. 20), could be used to obtain the shadow. For this demonstration the H and V projections are used (Fig. 20).

Draw the ray R through the point. R^v will pass through the V projection

of the point. R^h will pass through the H projection of the point. R^p will pass through the P projection of the point (Fig. 21).

(1) The shadow, being a point in V, has its H projection in the ground line, (the GL is the H projection of every point in V).

(2) The H projection of the shadow point must also be in R^h. (By definition, the shadow point is a point in the ray of light; therefore, its H projection s^h must be in R^h).

(3) The H projection of the shadow point must lie at the intersection of GL and R^h. (Since a point which is common to two lines can only be their intersection)

(4) The V projection s^v of the shadow point must lie in a perpendicular to the GL at s^h. (The two projections of any point lie in the same line perpendicular to the GL)

(5) The V projection of the shadow point must lie in R^v. (Reason similar to (2) above.)

(6) Therefore, the V projection of the shadow point must lie at the intersection of the perpendicular to the GL at s^h and R^v. (Reason same as (3) above)

Now a point in a plane is its own projection in the plane, and s^v is the shadow of the point a.

Although the above demonstration of the finding of the shadow of a point upon a coordinate plane presents the simplest illustration of the method of OBLIQUE PROJECTION, the procedure for the shadow of any point in space upon any surface, where this method applies, is exactly the same.

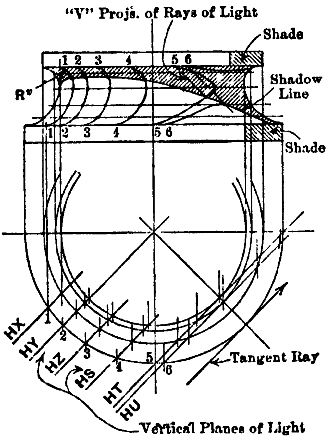

Fig. 22. The Slicing Method of Finding the Shadows of Points

To Find the Shadow of a Point by Slicing (Fig. 22). This method is quite simple, and is sufficiently explained by the diagram. The line, which is a circle, forming the top edge of the scotia, casts a shadow upon the surface of the scotia. The shadows of six points are found in order to plot the shadow line. The method is as follows: (*a*) Cut the line casting the shadow and the surface receiving the shadow with vertical PLANES OF LIGHT. (A plane which is assumed to be made up entirely of rays of light is called a plane of light.)

(*b*) Draw rays of light from the points, 1, 2, 3, 4, 5 and 6, which are cut on the line casting the shadow until they strike the slices made upon the surface of the scotia by the auxiliary planes. These are the shadow points of points 1, 2, 3, 4, 5 and 6. The curved line which joins them is the SHADOW LINE.

The slices are the traces of planes of light upon the surface of the scotia, and the shadow points are traces of rays of light in those planes, because a line lying in a plane has its traces in the traces of that plane.

The Shadow of a Line. Since a line is mathematically defined as the path of a point in motion, it follows that to find the shadow of any line upon any

surface implies simply the finding of the shadows of a sufficient number of successive positions of the point to plot the shadow of the line. In other words, find either by OBLIQUE PROJECTION or by SLICING the shadows of sufficient points in the line to plot the shadow of the line. Obviously the number and position of these points would depend upon, first, the kind of line casting the shadow, and second, the kind of surface receiving the shadow. For example:

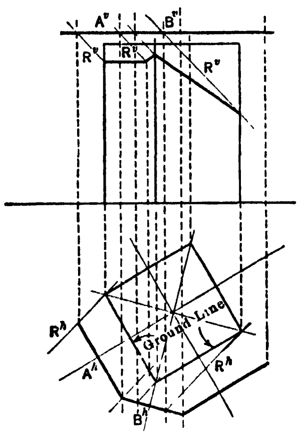

Fig. 23. The Shadow of a Straight Line upon a Plane Surface

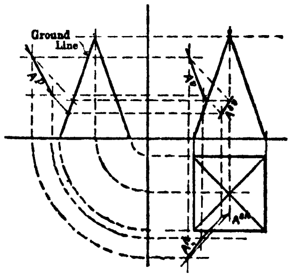

Fig. 24. The Shadow of a Straight Line upon a Plane Surface

(1) **To Find the Shadow of any Straight Line upon Any Plane Surface Which Can Be Projected as a Line** (Figs. 23 and 24), it is necessary to find

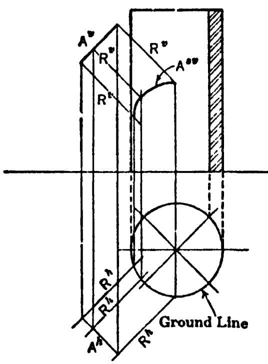

Fig. 25. The Shadow of a Straight Line upon a Single Curved Surface

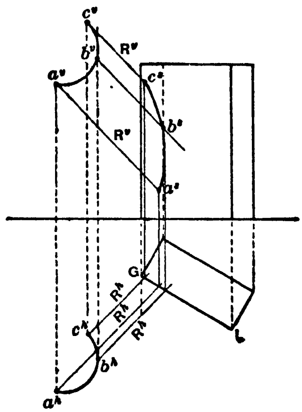

Fig. 26. The Shadow of a Curved Line upon a Plane Surface

the shadow of two points in the line by OBLIQUE PROJECTION and join them, since it is obvious that the shadow must be a straight line.

(2) To Find the Shadow of Any Straight Line upon any Single Curved Surface When the Surface Can Be Projected as a Line (Fig. 25), it is only necessary to find the shadow of at least three points by OBLIQUE PROJECTION to obtain the sense of the shadow line.

(3) To Find the Shadow of Any Curved Line upon Any Plane or Single Curved Surface When This Surface Can Be Projected as a Line (Fig. 26) would also necessitate more than two shadow points found by oblique projection.

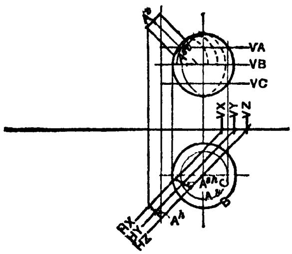

Fig. 27. The Shadow of a Straight Line upon a Double Curved Surface

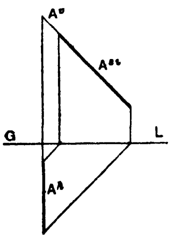
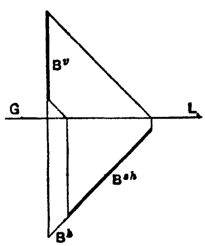
(4) To Find the Shadow of Any Straight or Curved Line upon Any Double Curved Surface or Any Other Surface Which Cannot Be Projected as a Line (Fig. 27) compels the use of the slicing method already described.

The fundamental thing which underlies the finding of the shadow of any line upon any surface by any method is, in the last analysis, the shadow of a point.

6. Standard Architectural Shadows

Standard Architectural Shadows. Certain straight lines in certain positions relative to the coordinates are constantly recurring as shade lines in architectural drawings. They occur so frequently and their shadows are so critical and expressive that they should be instantly recognized and their shadows correctly drawn. The circle, either in whole or in part, also occurs with great frequency in the shade lines of solids casting shadows. Like the straight line, it is constantly recurring in certain fixed positions relative to the coordinates,





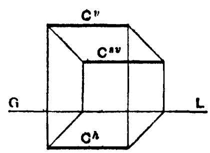


Fig. 28 Fig. 29 Fig. 30

Figs. 28, 29, 30. Projections of Lines, *A*, *B* and *C*, and Their Shadows upon the Co-ordinates

and if these shadows are at instant command the work of casting shadows is greatly facilitated.

The Shadows of Three Certain Straight Lines. For the purposes of explanation, these lines will be designated as follows: (1) Line *A* which is perpendicular to *V* and parallel to *H* (Fig. 28). (2) Line *B* which is perpendicular to *H* and parallel to *V* (Fig. 29). (3) Line *C* which is parallel to both *V* and *H* (Fig. 30).

Since A and B are, in effect, the same line, what is true of the shadows of A upon each of the two coordinate planes is simply reversed for B. However, for the sake of absolute clarity, they are considered as separate and different lines.

Fig. 31 illustrates the occurrence of these lines A, B and C in an architectural drawing. The shadows of these lines, when plotted carefully upon a drawing, convey much information, and are quickly and easily found.

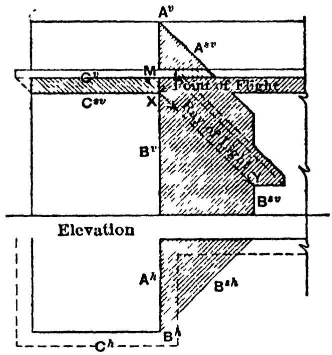

Fig. 31. Lines A, B and C, as they occur in Architectural Drawings

(1) The Shadow of a Line A which is Perpendicular to V, and Parallel to H (Figs. 28 and 31). As SEEN IN V PROJECTION, the shadow of this line is always a 45° line coincident in direction with the ray of light, regardless of what surfaces the shadow line crosses.

Actually, of course, this shadow line in space takes the contour of the surfaces which it crosses (Fig. 34). But the shadow line is the line of intersection of a plane of light through the line A and the shadow receiving surface. Since the line A is perpendicular to V, the plane of light through it is also perpendicular to V,

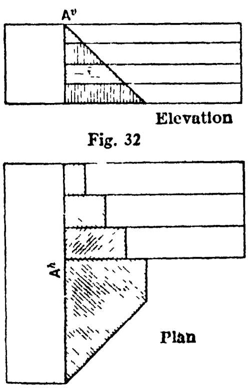

Fig. 32

Fig. 33

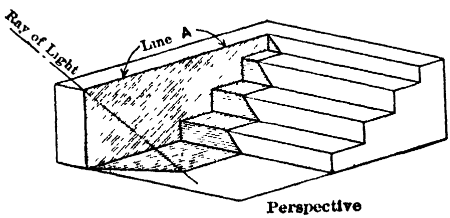

Fig. 34

Figs. 32, 33 and 34. The Shadow of the Line A upon a Flight of Steps

and any line in it will be projected in V coincidentally with the V projection of the conventional ray of light. Therefore, in elevation, the shadow line appears as an unbroken 45° line d-r (Fig. 32).

As SEEN IN H PROJECTION the shadow of the line A will express the contour of the surfaces it crosses (Fig. 33). The line A is parallel to the H coordinate,

and in that projection the relation to the coordinate is the same as in the case of line *C*. In Fig. 33 the surface is a flight of steps, and the rise and tread of the steps are expressed by the shadow line as exactly as a cross-section would show them.

(2) **The Shadow of a Line B which is Perpendicular to H, and Parallel to V** (Figs. 29 and 31). As SEEN IN *H* PROJECTION, the shadow of this line will be a 45° line *b–r* for the same reasons as the *V* projection of line *A*.

As SEEN IN *V* PROJECTION, the shadow of the line, *B*, like both *A* and *C*, will express the exact contour of whatever surface it crosses.

(3) **The Shadow of a Line *C*, which is Parallel to Both *V* and *H*** (Figs. 30 and 31), will express the contour of the surfaces which it crosses, as exactly as a cross-section, WHEN SEEN IN EITHER *V* or *H* PROJECTION.

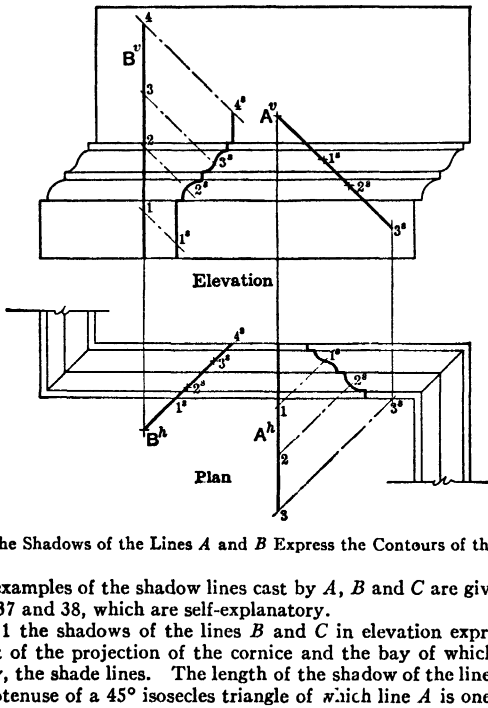

Fig. 35. The Shadows of the Lines *A* and *B* Express the Contours of the Moldings

Specific examples of the shadow lines cast by *A*, *B* and *C* are given in Figs. 31, 35, 36, 37 and 38, which are self-explanatory.

In Fig. 31 the shadows of the lines *B* and *C* in elevation express exactly the amount of the projection of the cornice and the bay of which they are, respectively, the shade lines. The length of the shadow of the line *A* is equal to the hypotenuse of a 45° isosceles triangle of which line *A* is one leg.

Fig. 35 illustrates how the shadows of line *A* and *B* may be used to express the profiles of moldings.

Fig. 36 shows the shadow of a line *C*, parallel to both *V* and *H* as it falls across the surface of a convex right circular cylinder, whose axis is perpendicular to *H*. The shadow which a square abacus casts upon the cylindrical shaft of a column is a typical example. The shadow itself in space is actually an ellipse, being an oblique section of a right circular cylinder, but it is so projected in *V* as to have equal axes. It is therefore a circle in *V* projection. The cen-

ter of the circle is a distance down upon the axis of the cylinder equal to the distance which the line C lies in front of the axis of the cylinder. This is best observed in P projection. Fig. 37 is similar to Fig. 36 except that the cylinder is now concave instead of convex. The lower half of the circle becomes the shadow of line C instead of the upper half, as in the case of the convex cylinder.

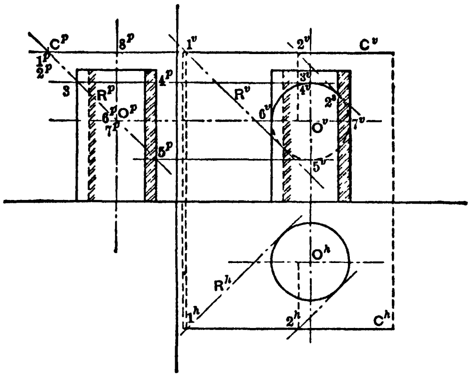

Fig. 36. The Shadow of a Line Which is Parallel to both V and H as it Falls across a Convex, Right Circular Cylinder, the Axis of Which is Perpendicular to H

Fig. 38 illustrates one of the most expressive of shadow lines. The shadow of this line B expresses exactly the slope of the roof, whatever it may be. If there are changes in the slope of the roof, as in a gambrel roof, this shadow will show it. Obviously, the shadow of a chimney will express upon the ele-

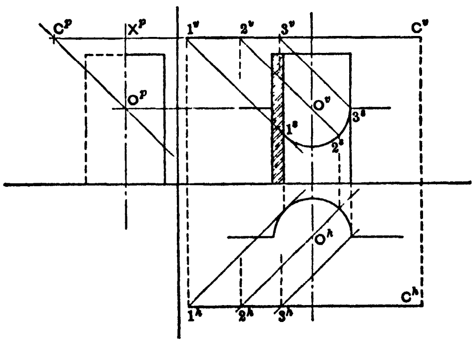

Fig 37. The Shadow of a Line Which is Parallel to both V and H as it Falls across a Concave, Right Circular Cylinder, the Axis of Which is Perpendicular to H

vation of a roof its exact slope so that a careful observer need not refer to any other drawing. No shadow better illustrates the importance of accurately cast shadows.

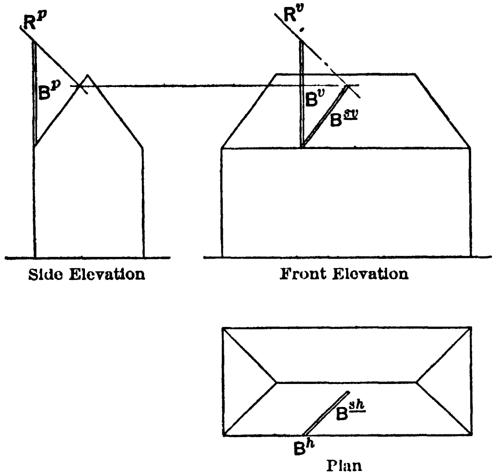

Fig. 38. The Shadow of a Vertical Line upon a Roof Plane

The Shadows of Nine Certain Circles. The shadows of nine circles, the planes of which lie in certain positions relative to the coordinates, follow:

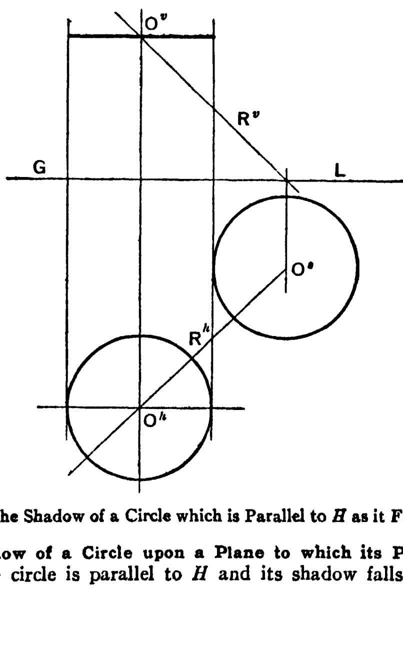

Fig. 39. The Shadow of a Circle which is Parallel to *H* as it Falls upon *H*

(1) The Shadow of a Circle upon a Plane to which its Plane is Parallel (Fig. 39). The circle is parallel to *H* and its shadow falls upon *H*. The

shadow in this instance will be another circle of the same radius. It is only necessary to find the shadow O^s of the center O. It will be noted, that the distance O-O^s, along R^h is equal to the diagonal of a square of which the distance O^v lies above the GL is a side.

(2) **The Shadow of a Circle, the Plane of Which is Parallel to One Coordinate as it Falls upon the Opposite Coordinate** (Fig. 40). The circle is parallel to H, and its shadow falls upon V. The shadow, in this instance, will be an ellipse, and it is most quickly and accurately plotted by the method of 8 POINTS AND 8 TANGENTS. A square $ABCD$ is circumscribed about the circle and its shadow found. The diagonals A^s C^s and B^s D^s are then drawn, obtaining the center O^s, from which points 1^s, 3^s, 5^s and 7^s are easily obtained. This gives 4 points and 4 tangent lines. The points 2^s, 4^s, 6^s and 8^s are then

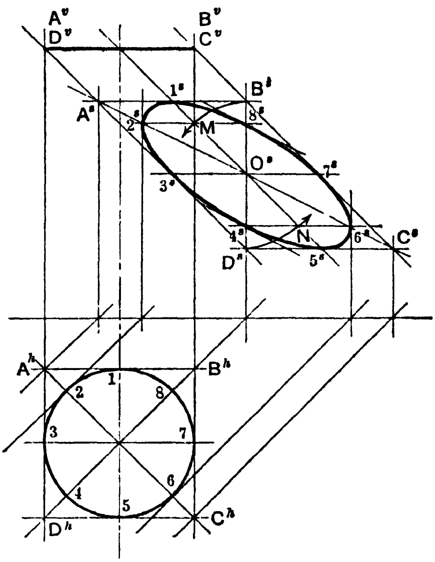

Fig. 40. The Shadow of a Circle Which is Parallel to H as it Falls upon V. Shadow Found by Method of "8 Points and 8 Tangents"

found as shown, and tangent lines, parallel to the diagonals A^s C^s and B^s D^s, are drawn. No attempt should be made to draw the ellipse until all 8 points and 8 tangents are plotted. This shadow can be found without the use of a plan, as indicated. With O^s as a center and O^sB^s as a radius, locate the point M, from which points 2^s and 8^s are obtainable, etc.

(3) **The Shadow of a Circle which Lies in a Profile Plane as it Falls upon V or H** (Fig. 41). The shadow, in this instance, is again an ellipse, which is also found by circumscribing a square about the circle and using 8 POINTS AND 8 TANGENTS. The method and its short-cut is made sufficiently clear by the drawing and reference to the preceding problem.

(4) **The Shadow of a Circle Which Lies in a Plane Parallel to H as it Falls upon a Vertical Plane Which is 45° h–l** (Fig. 42). In this instance, there is a difference between the shadow in space and its V projection which we obtain

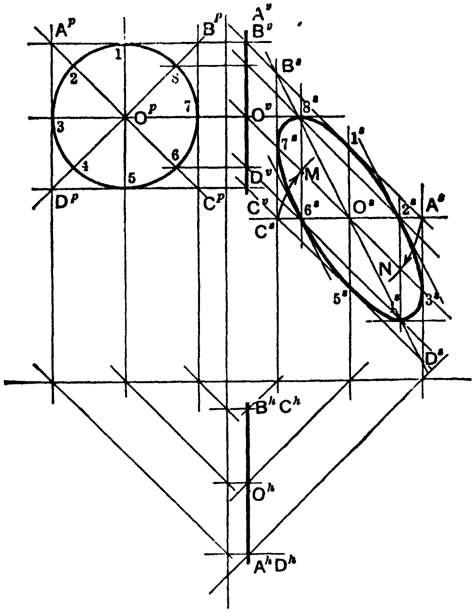

Fig. 41. The Shadow of a Circle Which is Parallel to *P* as it Falls upon *V*. Shadow Found by Method of "8 Points and 8 Tangents"

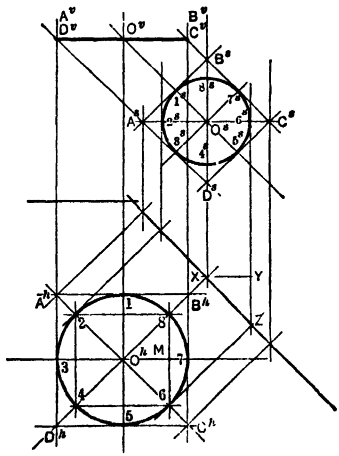

Fig. 42. The Shadow of a Circle upon a Vertical Plane (45° B–L)

Actually the shadow is an ellipse. But its horizontal axis is so foreshortened (in projection) as to make the ellipse appear in V projection as a circle whose radius is equal to $\frac{1}{2}$ the side of the inscribed square 2–4–6–8. The proof for this last statement becomes evident when Fig. 42 is studied. Isosceles triangles O^h M–6 and X–Y–Z are equal. From this it can be seen that $O^hM = XY = O^s6^s$.

(5) The Shadow of that Great Circle of a Sphere which Lies in a Plane Perpendicular to the Ray of Light as it Falls upon Either Coordinate Plane (Fig. 43). This circle is at once recognized as the shade line of a sphere (Fig. 14). Its two projections are ellipses and the shadow is an ellipse. The shade line is obtained by a variation of SLICING, called the METHOD OF SYMMETRY FOR SPHERES. (See, also, Figs. 67 and 68) Slice the sphere by 5 planes:

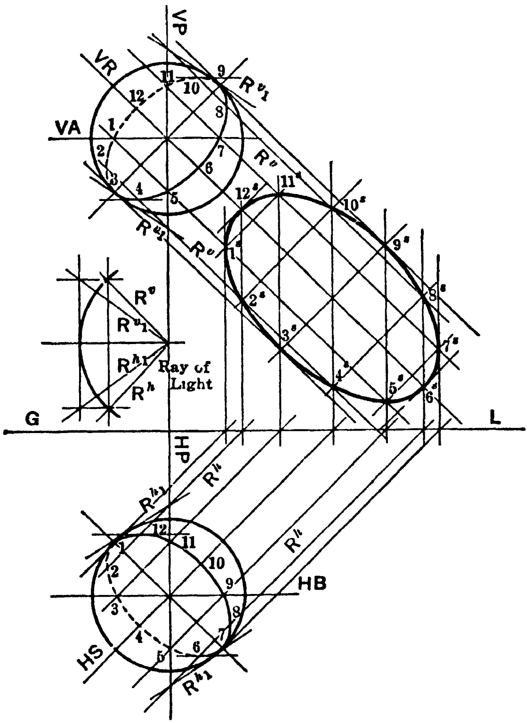

Fig. 43. "Shade Line" Obtained by the Method of "Symmetry for Spheres" "Shadow Line" Found by Casting the Shadows of 12 Points

(1) the profile plane P, (2) the horizontal plane A, (3) the vertical plane B, (4) the auxiliary plane of light R which is perpendicular to V, (5) the auxiliary plane of light S which is perpendicular to H. Tangent rays are then drawn (in projection) to sections P, A and B and the points, 5 and 11, 1 and 7, 3 and 9 thus obtained. Tangent rays (revolved), drawn to the sections R and S when revolved parallel to H and V, respectively, obtain the points 12 and 6,

10 and 4, respectively. These four points are critical points in the shade line, inasmuch as 10 is the highest point, 4 the lowest, 12 nearest to V and 6 furthest from V. The other two points 2 and 8 are plotted by symmetry.

The shadow of the shade line is most quickly found by finding the shadows of the twelve points and joining them.

It will be noticed that the major axis of the ellipse of shade casts the minor axis of the ellipse of shadow and is equal to it. The minor axis of the ellipse of shade casts the major axis of the ellipse of shadow and is equal to $\frac{1}{3}$ its length.

The Shadows of Circles upon Surfaces Other than Plane Surfaces. In the practical work of casting architectural shadows, it frequently happens that we are confronted with the problem of casting the shadow of a circle or part of a circle upon surfaces other than plane surfaces (see Fig. 102). But almost without exception the problem presented is one which is constantly recurring, and therefore, if once understood, is quickly solved. Examples of such problems will now be given.

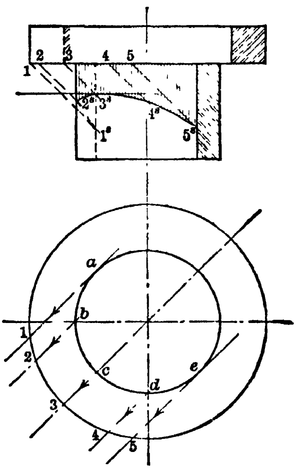

Fig. 44. The Shadow Cast by a Cylindrical Cap upon a Cylindrical Shaft below

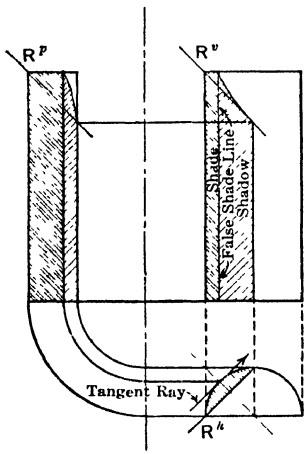

Fig. 45. The Shadow within a Hollow Cylinder

(6) The Shadow of a Circle upon the Surface of a Convex Right Circular Cylinder (Fig. 44). This problem occurs with great frequency as the shadow of a cylindrical cap overhanging a cylindrical shaft. The method of solution has been explained elsewhere. (See Fig. 52.) A projecting band of molding upon a cylindrical wall surface would be a typical example. The shadow is extremely useful in expressing the curvature of the surface.

(7) The Shadow of a Circle upon a Concave Right Circular Cylinder (Figs. 45 and 46). This problem arises in the shadow in a hollow cylinder (Fig. 45), and the shadow within a barrel vault (Fig. 46).

(8) The Shadow of a Circle upon the Surface of a Hollow Cone (Fig. 47). Variations of this problem are of frequent occurrence. The solution is similar to the first method for the head of a niche (Fig. 49).

(9) The Shadow of a Circle upon the Surface of a Hollow Hemisphere (Fig. 48). The most common occurrence of this shadow is that cast within

a spherical-headed niche by the circular rim of the niche. When Figs. 45 and 48 are combined we have the entire shadow which occurs within a spher-

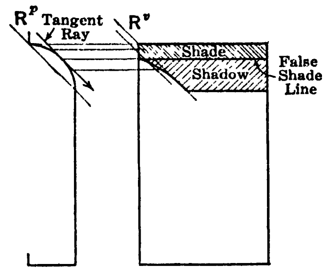

Fig. 46. The Shadow within a Barrel Vault

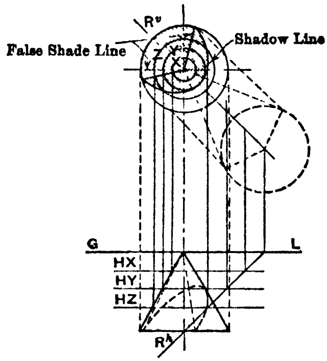

Fig. 47. The Shadow within a Hollow Cone

ical-headed niche. Figs. 49, 50 and 51 illustrate three methods whereby the shadow in the head of a niche may be obtained. They are all applications of

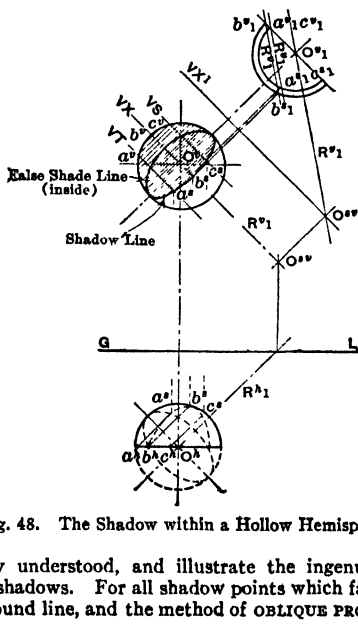

Fig. 48. The Shadow within a Hollow Hemisphere

principles already understood, and illustrate the ingenuity which can be shown in finding shadows. For all shadow points which fall below the spring line we have a ground line, and the method of OBLIQUE PROJECTION will serve.

First Method Auxiliary Planes Parallel to the Line Casting the Shadow (Fig. 49) shows a method whereby auxiliary vertical planes X, Y and Z are used to cut lines x, y and z from the niche. The shadow of the rim upon each of these planes is a circle since the rim is a circle parallel to V. The points where these circles cut the lines x, y and z are points in the shadow of the rim

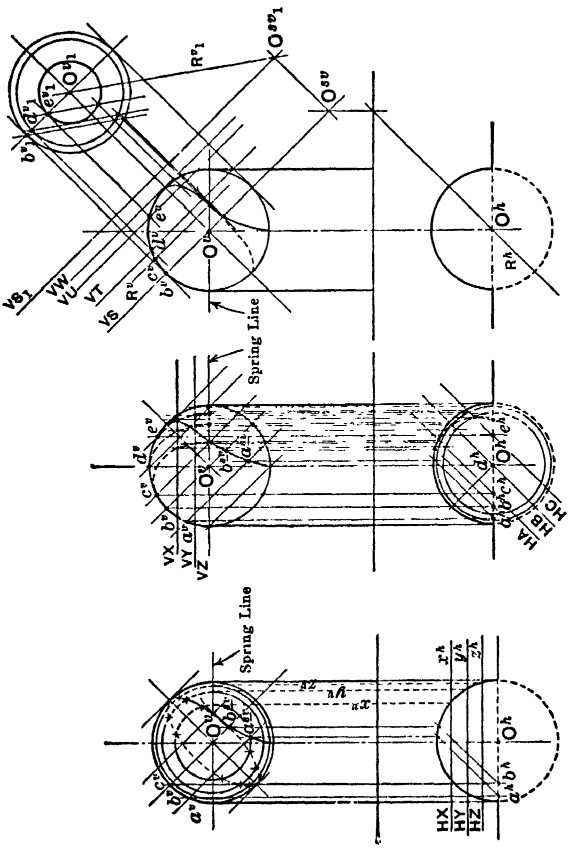

Fig. 49

Fig 50

Fig. 51

Figs. 49, 50, 51. The Shadow Line within a Spherical-Headed Niche

and in the head of the niche since the lines x, y and z are in the head of the niche.

Second and Third Methods: Slicing (Figs. 50 and 51). These are two variations of the SLICING METHOD, already explained, of finding this shadow. In Fig. 50 the rays of light (in projection) are immediately applied to the projected sections, and shadow points obtained. In Fig. 51 both the slices and the ray of light are revolved into the coordinate plane before the shadow points are obtained. (See Fig. 48.) They are then counter-revolved. This method

is sometimes called the REVOLVED PLANE method, but is really but a variation of the slicing method.

7. Practice of Casting Shadows

Practice of Casting Shadows. The ultimate aim of the science of shades and shadows is to cast the shadow of any geometric surface upon any other geometric surface. Since architectural design is fundamentally the art of arranging geometric surfaces in such combined relations that their light effects (lights, shades and shadows) will be pleasing, it appears that each rendered drawing presents new problems to be solved. Equipped with all the necessary knowledge, it now becomes necessary to be resourceful. Every drawing to be rendered will contain objects the shadows of which cannot be cast either by oblique projection or slicing alone. Even the shadows of single objects may be most advantageously cast by the use of both methods applied to different parts (as in column caps or bases). There are no fixed rules. The Fundamental Principles outlined in Part 4 must be thoroughly assimilated. The Standard Shadows described in Part 6 must be at instant command. Even then, after the Theory of Casting Shadows (explained in Part 5) is completely understood, the practical work of casting shadows may be greatly simplified by ingenious short-cuts or expedients invented to meet new conditions. They do not involve any new method of casting shadows, but may reduce some complex shadow to several simpler ones (Figs. 55A and 55B), or may simplify the procedure, as in Fig. 57. Examples given below are but a few of the better-known and generally used.

(1) Dispensing with One Projection. In the method of oblique projection for the shadow of a point shown in Fig. 20, it is obviously only necessary to have the V projection and know how far the point is from V. The plan is unnecessary, since the shadow is a distance horizontally to the right of the point equal to the distance the point lies in front of V, and of course upon the ray.

Similarly, for a shadow upon H, the elevation is unnecessary. The convenience of this in actual practice where plan and elevation may be upon different sheets and at different scales is self-evident.

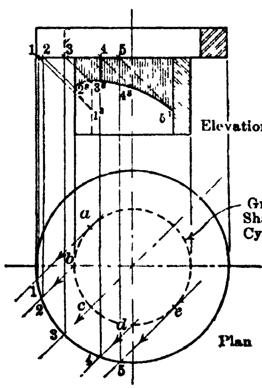

Fig. 52. The Shadow of a Cylindrical Cap Overhanging a Cylindrical Shaft by "Critical Rays"

(2) Critical Rays (Figs. 52 and 53) are used to illustrate a device used in many instances to simplify the work of finding shadows of lines. In Fig. 52 it is required to find the shadow of a cap overhanging a cylindrical shaft. The lower edge of the upper cylinder is, of course, the shade line for the shadow upon the shaft. Instead of taking points at random and finding their shadows, in order to plot the shadow line, certain rays are drawn backward from the CRITICAL SHADOW POINTS a, b, c, d and e. It is found that the

points 1, 2, 3, 4 and 5 are the points in the shade line which cast shadow points *a*, *b*, *c*, *d* and *e*. Their *V* projection is then obtained and shadow points are thus obtained at 1^s and 5^s which are on the shade lines of the cylindrical shaft, at 2^s which is on the contour element, at 4^s the *V* projection of the axis of the cylindrical shaft, and at 3^s which point is cast by the ray which would pass through the axis of the cylinder. This shadow point 3^s is the

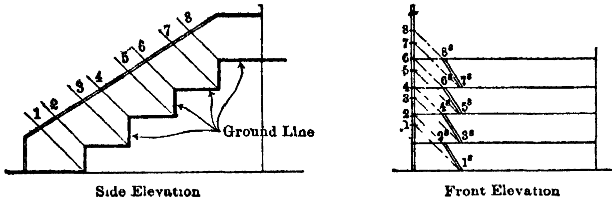

Fig. 53. The Shadow of a Handrail upon a Flight of Steps by "Critical Rays"

highest point in the curve of the shadow line because that ray of light travels the shortest distance. A ray slightly to either side would travel further and the shadow point be lower. It will be noted that points 1^s and 5^s are at the same level, and 2^s and 4^s are also a pair.

Fig. 53 illustrates how this same device of CRITICAL RAYS may be used in determining shadow lines which break across several adjacent surfaces. The example given is the shadow of a sloping hand-rail beside a flight of steps. In this instance, both the treads and the risers are projected as lines at the same time only in the side-view or *P* projection, so that projection is most convenient to use as a ground line for the shadows. Only the critical shadow points 1 to 8 inclusive are found. In the practice of casting shadow many opportunities are presented for the exercise of ingenuity as shown by this method of critical rays.

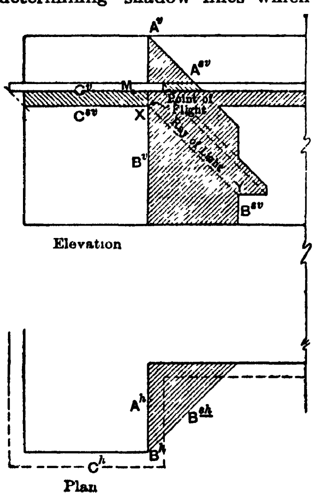

Fig. 54 The Point of Flight

(3) **The Point of Flight.** Fig. 54 illustrates another device which is exceedingly useful in the practical work of casting shadows. The POINT OF FLIGHT is the point where the shadow of line *C* jumps from one surface to another. The ray of light passing through the point of flight *x*, which is the last shadow point of the line *C* upon the first surface, obtains the point *y* in the silhouette of the shadow. The point *y* is the first point of the shadow of the line *C* upon the second surface. In other words, the ray of light from the point *M* in the line *C*, touches the vertical edge *B* at *x*, the point of flight, and continues on to strike the wall surface at *y*. The figure illustrates a characteristic use of the ray of light through the point of flight which has many obvious advantages. There is no more important step to be learned in practical shadow-casting than frequent use of this device. It simplifies the work tremendously.

(4) **Auxiliary Shadows** (Figs. 55A and 55B). In architectural drawing a large group of figures to be represented are solids of revolution with their axes commonly perpendicular to H or V or parallel to GL It is therefore possible, without much difficulty, to determine their shadows by constructing

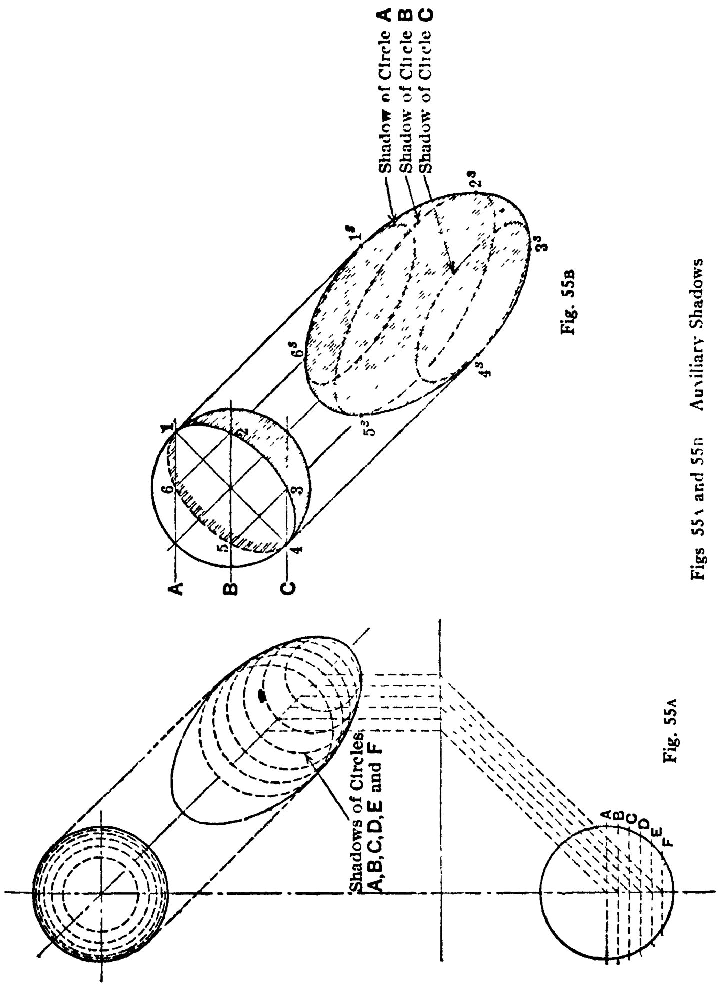

Fig. 55B

Fig. 55A

Figs 55A and 55B Auxiliary Shadows

the shadows of a few principal cross-sections, since every cross-section would be circular. Figs. 55A and 55B are simple illustrations of the possibilities of this method. Its application facilitates the work by use of the auxiliary lines whose shadows may be cast readily and accurately. The principles upon which the method depends are made sufficiently clear by the drawings.

(5) Circumscribing or Inscribing Surfaces (Figs. 56 and 57). This application depends upon the principle that, at a point of tangency of two surfaces, whatever is true of one surface is also true of the other for such a point is common to both. In Fig. 56 the shade line of the sphere is found by circumscribing cones, and in Fig. 57 the shadow of the sphere is found by inscribing a cube. The drawings are sufficient explanation.

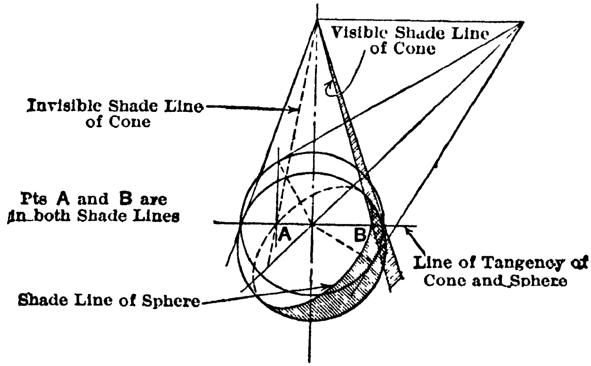

Fig. 56. A Cone Circumscribed about a Sphere

(6) Pyramids and Cones. Fig. 58 shows how finding the shade and shadow of a pyramid is simplified by producing the pyramid until its base rests in *H*. The new base is then its own shadow and need not be cast. The shade surfaces of the original pyramid are the same as those of the new one. The shadow of the base of the first pyramid is then easily found. The same would

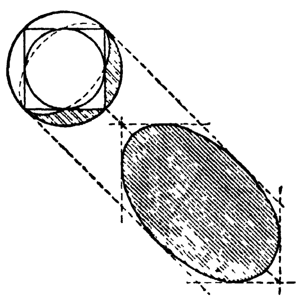

Fig. 57. A Cube Inscribed within a Sphere

apply to cones (Fig. 59). Fig. 56 shows a quick way of finding the shade line of a cone by the SHADOW COMPLETE method.

(7) Niches (Figs. 49, 50, 51). The three methods already explained, showing how the shadow within a spherical-headed niche is found, are further examples of the ingenuity which must be shown in the practice of casting shadows.

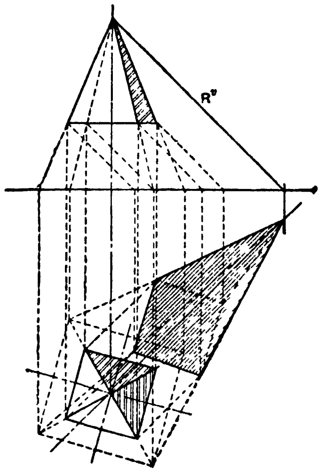

Fig. 58. Producing a Pyramid

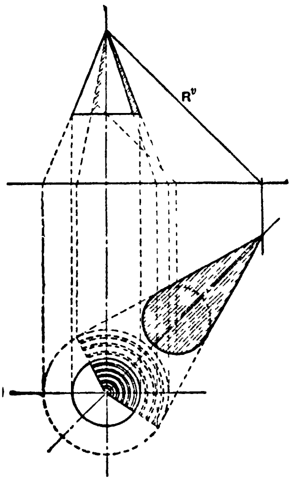

Fig. 59. Producing a Cone

8. Determining and Forecasting Shade Lines

Determining and Forecasting Shade Lines. The primary and most important function of the science of shades and shadows is that of determining shade lines. It has been shown that, in the final analysis, the shadow line of any object upon any surface is cast by the shade line of that object (Fig. 14). Therefore, it follows that it is only necessary to be able to find the shadows

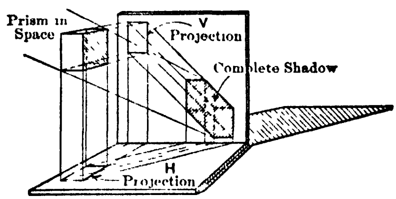

Fig. 60. Casting the "Shadow Complete"

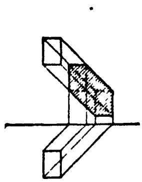
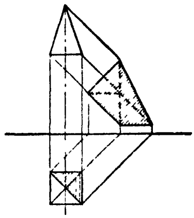
of points in order to find any shadows, once the shade line has been determined. Of course the shadow line of any object upon any surface could be approximated by casting the shadows of sufficient random points in its surface and joining the outermost by a line (Fig. 60). But the labor of finding a great number of unnecessary shadow points and the uncertainty of the accuracy of the results for more complex solids compel a more scientific procedure. Therefore, determining the shade line of an object not only definitely outlines the light and shade surfaces of the object itself, but if the shade line can possibly be forecast, the work of finding the shadow line becomes greatly simplified.

Shadow Complete Method (Figs. 61, 62, 63). The simplest method of determining the shade line of any object is to trace back from the outline of its COMPLETELY CAST SHADOW, and discover which points in the surface of the object cast the shadow line. Theoretically it will apply to any solid, and its only use is to determine the light and shade portions of the surface of the object, since the shadow is already obtained. This method is particularly applicable to cones (Fig. 63).



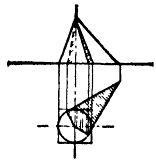
Prism

Fig. 61



Pyramid

Fig. 62

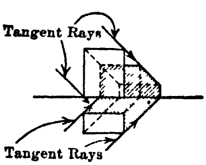


Cone

Fig. 63

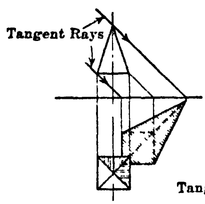
Figs. 61, 62 and 63. "Shadow Complete" Method of Determining Shade Line as Applied to Prisms, Pyramids and Cones

Tangent Ray Method (Figs. 64, 65, 66). Any application of the science of shades and shadows which seeks to predetermine or forecast the shade lines of objects before their shadow is cast, must devise ways for finding sufficient points upon their surfaces where rays of light are tangent, and connect those points of tangency and thus plot the shade lines. Sometimes this is so simple and direct as to amount practically to inspection (Figs. 64, 65, 66). It is then called the TANGENT RAY method. It consists of applying the pro-



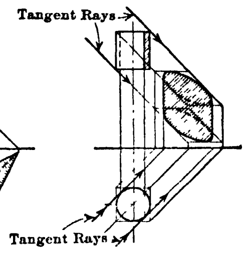
Prism

Fig. 64



Pyramid

Fig. 65



Right Cylinder

Fig. 66

Figs. 64, 65 and 66. "Tangent Ray" Method of Predetermining Shade Line as Applied to Prisms, Pyramids and Cylinders

jections of rays of lights to surfaces, on the coordinate where those surfaces are projected as lines. It will be apparent at once whether the surface is reached by light or not. The shade line divides the surfaces of light from the surfaces of shade thus determined.

Obviously, this method will apply only to solids the surfaces of which can somewhere be projected as lines.

Slicing and Revolved Plane Methods (Figs. 67 and 68). In both of these methods, auxiliary planes of light are used to cut critical sections from the surface of the solid. These sections are either projected (SLICING method,

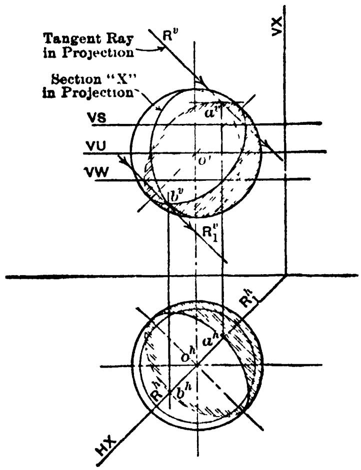


Fig. 67. The Slicing Method

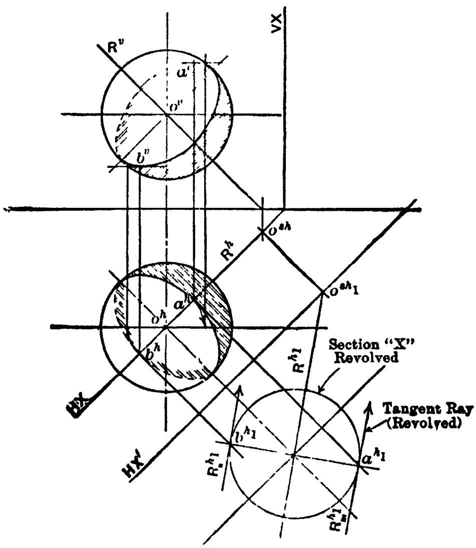

Fig. 68. The Revolved Plane Method

Fig. 67), or revolved into a coordinate (REVOLVED PLANE method, Fig. 68). The tangent ray is then drawn to the section of the surface (ray in projection in the slicing method and revolved ray in the revolved plane method). This obtains successive points of tangency of rays, hence points in the shade line. Although separate names have been given these methods, they are really one method, the slicing method. Both slicing and revolved planes are applicable to any solid whatever, but the revolved plane method is particularly useful when the object is a double curved surface of revolution. The sections cut by the auxiliary planes then are all circles, and when revolved into one of the

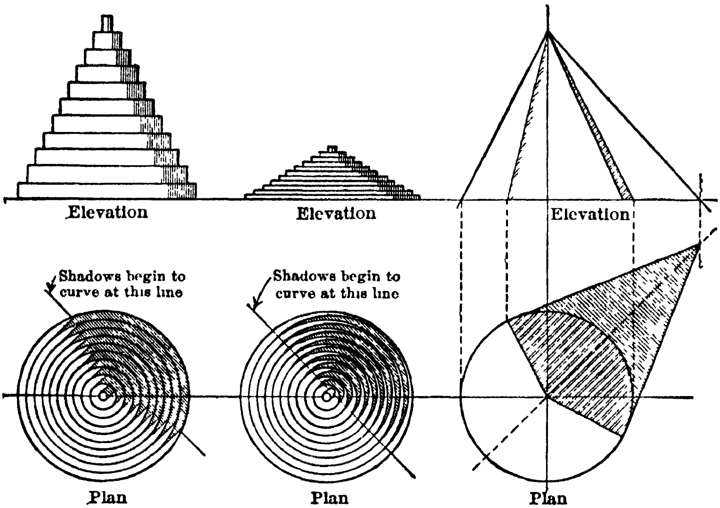

Fig. 69 Fig. 70 Fig. 71

Figs. 69, 70 and 71. The Paradox of Shade Line

coordinate planes, can be drawn with a compass. Fig. 67 illustrates the slicing method as applied to a sphere, and Fig. 68 illustrates the revolved plane method also applied to a sphere. In practice, the complete shade line of a sphere is found by the revolved planes method of slicing. (See Fig. 43) Because symmetrical points are found, this variation of the slicing method is called the METHOD OF SYMMETRY FOR SPHERES.

The Tangent Planes Method, applicable to all convex double curved surfaces such as spheres, torii, etc., consists briefly in finding where planes of light are tangent to the surface. If a plane of light is tangent to the surface, it is a geometrical truth that a ray of light is tangent at the same point, hence that point is in the shade line of the object. A succession of such points constitutes the shade line. But since the slicing method applies in every case, this method is rarely used.

The Paradox of Shade Line (Figs. 69, 70 and 71). An interesting paradox arises concerning the shade lines of right circular cylinders and right circular cones (both axes perpendicular to *II*). The shade line of the cylinder is determined by the tangent ray in *H* projection (Fig. 66). The shade line of the

cone must be found by the shadow complete method (Fig. 63). The tangent ray method does not apply to the cone. If a number of cylinders are piled up in a conical manner (Figs. 69 and 70), the shade line upon each will be on the corner, and the complete shade line of the pile will be a broken line or series of steps at the corner, irrespective of its steepness and the size of the steps. Even if they are so small that the surface looks almost smooth (Fig. 70), and the pile of cylinders looks like a cone, the shade line will not change, although the shade line upon the cone (Fig. 71), which the pile of cylinder simulates, may vary anywhere from being a single line where a ray of light is exactly tangent up to the two corner elements, according to the slope of the cone. In the latter case the cone has become a 90° cone or a right circular cylinder.

9. Vocabulary

Vocabulary. Repeatedly to work out the shade lines and shadow lines of the elements constantly found in architectural drawings would only involve a considerable amount of unnecessary labor, once their derivations are understood. Since much architectural detail is vocabulary, and can be reduced by convention to certain definite geometric forms already tabulated (Figs 6 to 11, inclusive), we have constant repetition of certain objects casting shadows and certain surfaces receiving shadows.

It is, therefore, of the greatest fundamental importance to acquire from a study of shades and shadows a vocabulary of projections of shade lines and shadow lines of these constantly recurring architectural forms, so that both the rendering and the reading of architectural plans and elevations may be facilitated.

These surfaces which are constantly casting and receiving shadow, alone and in combinations, occur in column caps and bases, cornices, pediments, moldings, brackets, modillions, balusters, etc. Their shade lines and shadow lines together with those of the orders (Doric, Ionic, Corinthian, and Composite) compose an extensive vocabulary. Intelligent use of this vocabulary presupposes a complete understanding of its derivation. In the use of this vocabulary there can be no compromise. The shade lines and shadow lines must be correctly drawn, in order that they fulfil their primary purpose, i.e., to convey accurate information. Although an approximation may seem to suffice, only absolute accuracy will be true. The critical and important points in the shade and shadow lines may be so subtle that, although the memory may be relied upon for an approximation, when absolute accuracy is sought either the problem should be correctly solved or visual reference made to a previous correct solution.

Following is a reference vocabulary of miscellaneous architectural shades and shadows.

SPECIFIC GRAVITY

The Specific Gravity of a substance is the number which expresses the ratio that the weight of a given volume of the substance bears to the weight of the same volume of distilled water at a temperature of 62° F.; or, the specific gravity of a body is equal to its weight divided by the weight of an equal volume of water. The specific gravity of a substance, multiplied by the weight of a cubic foot of water, will gi e the weight of a cubic foot of the given substance. The weight of a cubic foot of water, at 62° F. and at the sea-level, is about 62.355 lb.* The specific gravity of a solid substance may be determined by first weighing a portion of it in air and then in water and dividing the weight in air by the loss of the weight in water; the quotient is the specific gravity required.

Example. A piece of granite weighs 5 32 lb. in air; when immersed in water it weighs 3 32 lb.

Solution. Weight in air (5.32 lb) divided by loss of weight in water (2 lb) = 2.66, the specific gravity.

$$2.66 \times 62.355 \text{ lb} = 165.84 \text{ lb} = \text{weight per cubic foot}$$

Note. 1 cu ft = 7.48 gal.

* The textbooks differ slightly in regard to this value.

Specific Gravities and Weights per Cubic Foot of Various Substances *

The basis for specific gravities is pure water at 62° F., barometer 30 in. Weight of 1 cu ft of water, 62.355 lb	Average specific gravity. Water = 1	Average weight of 1 cu ft lb
Agate . . . 2.5 to 2.8	2.6	162.1
Air, atmospheric at 60° F, under pressure of one atmosphere, or 14.7 lb per sq in, weight $\frac{1}{815}$ the weight of water	0.00123	0.0767
Alabaster, carbonate . . . 2.61 to 2.76	2.68	167.1
Alcohol, absolute, at 32° F	0.794	49.5
Alcohol, 50 per cent	0.934	58.24
Alcohol, 95 per cent	0.815	50.82
Alcohol, commercial	0.833	51.95
Alder, dry† . . . 0.42 to 1.01	0.55	34.3
Alum	0.53	33.0
Aluminum, hammered	2.75	171.7
Aluminum, drawn	2.68	167.1

Amber	1.08	67.4
Ambergris	0.87	54.3
Ammonia, 60° F	0.894	55.81
Antimony, cast	6.70	418.0
Antimony, native	6.67	416.0
Apple-wood, dry† . . . 0.66 to 1.25	0.75	46.8
Arsenic . . . 5.7 to 5.8	5.73	357.3
Asbestos . . . 2.1 to 3.0	2.81	175.0
Asbestos sheathing-paper	1.20	75.0
Ash, American white, dry†	0.61	38.0
Ashes of soft coal, solidly packed	0.70	40 to 45
Asphalt, for street-paving	1.60	100.0
Asphaltum . . . 1.11 to 1.23	1.15	69 to 75
Ballast, brick, gravel	1.79	111.6
Bamboo, dry†	0.36	22.5
Barium	3.88	242.0
Barytes	4.45	277.5
Basalt or trap-rock, average	2.96	184.6
Jersey City, N. J	3.00	187.1
Duluth, Minn	2.95	184.0
Staten Island, N. Y	2.86	178.3
Beech, dry† . . . 0.65 to 1.12	0.74	46.0
Beeswax	0.95	59.0
Benzine	0.69	43.0
Beer	1.04	64.9
Birch, dry† . . . 0.52 to 1.08	0.65	40.6
Bismuth, cast . . . 9.76 to 9.90	9.82	612.3
Blood, at 32° F	1.06	66.2
Bone . . . 1.8 to 2.0	1.90	118.6
Borax . . . 1.7 to 1.8	1.75	109.2
Boxwood, French, dry†	1.33	83.0

* The values given in this table are AVERAGE values.

† The word "dry" in this connection indicates that the wood contains not more than 15% of moisture. Green timbers usually weigh from one-fifth to nearly one-half more than dry; ordinary building-timbers, tolerably seasoned, one-sixth more.

Sand, or pure quartz, voids full of water		118 to 129
Sand, of pure quartz, very large and small grains, dry		117 0

* The values given in this table for specific gravities and for weights per cubic foot are AVERAGE values.

† The word "dry" in this connection indicates that the wood contains not more than 15% of moisture. Green timbers usually weigh from one-fifth to nearly one-half more than dry; ordinary building-timbers, tolerably seasoned, one-sixth more.

Specific Gravities and Weights per Cubic Foot of Various Substances * (Continued)

The basis for specific gravities is pure water at 62° F., barometer 30 in. Weight of 1 cu ft of water, 62.355 lb	Average specific gravity. Water = 1	Average weight of 1 cu ft lb

WIRE-GAUGES* AND METAL-DATA

A Wire-Gauge is a method of designating the diameter of wires or the thickness of sheets of metal by the numbers of a table arranged on a certain fixed basis. There are at the present time several gauges, resulting in great confusion, Table XIII, Chapter XI, gives the diameters of the gauges in common use. The only legal gauge in this country is the United States standard gauge. It is used by most of the manufacturers of sheet iron and steel and tinplate. The Brown & Sharpe gauge is commonly used for designating size of copper wires, and for sheet copper and brass. Nearly all copper wire, bare and insulated, is ordered, manufactured, and carried in stock in accordance with this gauge. This might be called the Copper Wire Gauge. The American Steel & Wire Company uses the old Washburn & Moen and Roebling gauges for all their steel and iron wire and also for wire nails. The sectional areas for these gauges are given in Table XIV, Chapter XI, and the table given in this section, taken from the Roebling and American Steel & Wire Company's lists. When placing orders for sheets and wire, it is always best to specify the weight per square or linear foot or the thickness or diameter in thousandths of an inch or in circular mils. The gauge for steel wire, used by the J. A. Roebling's Sons Company, is given in Table XIV, Chapter XI, and the circular-mil-gauge in Table III, Chapter XXXIV. The gauge used by this company is the same as the Washburn & Moen gauge, or the American Steel & Wire gauge, except that the diameters in most cases are given to the nearest mil. This gauge is so generally used for steel wire that it is sometimes called the Steel Wire Guage or the Market Wire Gauge. The Birmingham Wire gauge is the same as Stubs' Iron-Wire gauge, but entirely different from Stubs' Steel-Wire gauge. Galvanized telegraph and telephone-wire, both bare and insulated, and galvanized armor-wire are usually designated by this gauge. Its use is not very extensive and is becoming less. The new British Standard gauge is the legal standard for Great Britain and is used there for all kinds of wire. Its use in this country is very limited. It is known, also, as the English Legal standard gauge and the Imperial Wire gauge.

* See Chapter XI, Article 7.

* For iron wire, the values in columns 6 and 7 should be multiplied by 0.98 and for copper wire, by 1.12.

Kinds of Wire Manufactured by the American Steel and Wire Company

Market-wire, Nos. 0000 to 18.

Annealed stone-wire or weaving-wire, Nos. 16 to 47.

Tinned market-wire, Nos. 0 to 18.

Tinned stone-wire, Nos. 16 to 40.

Gun-screw wire, finished with great care as regards roundness and exactness to gauge, Nos. 18 to 50.

Machinery-wire, Nos. 00000 to 18.

Cast-steel wire, ½-in diameter, down to No. 26.

Drill and needle-steel wire, Nos. 12 to 25.

Welding wire:

for Electric Welding,	Nos 3 to 10
for Electric or Acetylene Welding,	Nos. 2 to 7
for Acetylene Welding,	Nos. 2 to 16

The term MARKET-WIRE applies to the ordinary and most used forms of Bessemer ANNEALED, BRIGHT, GALVANIZED, TINNED and COPPERED wires.

Galvanized-Iron-Wire Strand. See Chapter XI.

Rules for Estimating the Weight of any Piece of Wrought Iron, Steel or Cast Iron

Wrought Iron.

One cubic foot of wrought iron weighs	480 lb
One square foot, one inch thick, weighs	40 lb
One square inch, one foot long, weighs	$3\frac{1}{3}$ lb

To find the weight per square foot of sheet iron, multiply the thickness in inches by 40.

To find the weight per linear foot of bars of any section, multiply the cross-sectional area in square inches by $3\frac{1}{3}$.

Steel.

One cubic foot of steel weighs	489.6 lb
(Or just 2% more than wrought iron.)	
One square foot, one inch thick, weighs	40.8 lb
One square inch, one foot long, weighs	3.4 lb

To find the weight per linear foot, of bars of any section, multiply the cross-sectional area in square inches by 3.4; or, if the weight is known, the exact sectional area may be obtained by dividing by 3.4.

Cast Iron.

One cubic foot of cast iron weighs	448.9 lb
One square foot, one inch thick, weighs	$37\frac{1}{2}$ lb
One square inch, one foot long, weighs	$3\frac{1}{8}$ lb
One cubic inch weighs	0.26 lb

The weight of irregular castings must be estimated by the cubic inch.

Rules for Weights of Castings

Multiply the weight of the pattern by 18 for cast iron, 13 for brass, 19 for lead, 12.2 for tin, 11.4 for zinc, the product is the weight of the casting.

Reduction for Round Cores and Core-Prints

Rule. Multiply the square of the diameter by the length of the core in inches, and the product multiplied by 0.017 is the weight of the pine core to be deducted from the weight of the pattern.

Shrinkage in Castings

Pattern-makers' Rule (of an inch longer per linear foot):

Cast iron	$\frac{1}{8}$
Brass	$\frac{3}{16}$
Lead	$\frac{1}{8}$
Tin	$\frac{1}{12}$
Zinc	$\frac{3}{16}$

* Birkmire.

† a and b = either side, outside measurement. $2a + 2b$ = number. Allowance has been made in this table for corners counted twice.

Example. What is the weight per linear foot of a 12 by 16 by 1 in thick column?

Solution. $2a + 2b = 24 + 32 = 56$. Opposite this number, under 1-in-thick metal, we find 162.5, or weight per linear foot of a column 12 by 16 by 1-in-thick.

Note. For flanges, brackets, etc., calculate the cubical contents of same and multiply by 0.26; cast-iron averages 448.9 lb per cu ft.

For larger plates take size of plate ONE-HALF smaller and multiply by 2. Thus a plate 28 by 32 in will weigh twice as much as one 14 by 32 in. For plates more or less than one inch in thickness multiply weight of plate by thickness in inches.

Approximate Weights of Square-Ribbed Cast-Iron Column-Bases

The following table, giving the weight of cast-iron column-bases, will be useful when estimating the steel and iron in tall buildings.*

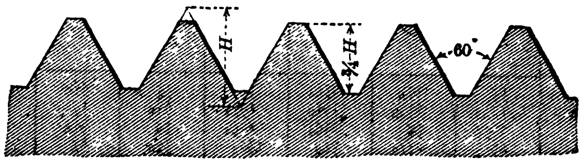
Size of square base, in	Weight, lb	Size of square base, in	Weight, lb
22×22	600	32×32	1 340
24×24	750	34×34	1 450
26×26	880	36×36	1 600
28×28	1 020	38×38	1 720
30×30	1 180	40×40	1 850

* H. G. Tyrrell, in Architects and Builders Magazine.

Screw-Threads, Nuts, and Bolt-Heads

Standard Screw-Threads

Recommended by Franklin Institute, December 15, 1864, and adopted by Navy Department of the United States; by the R. R Master Mechanics' and Master Car-Builders' Associations; by Jones & Laughlin Steel Company; and by many other of the prominent engineering and mechanical establishments of the country.



Angle of thread 60°. Flat at top and bottom 1/8 of pitch.

Diam of screw, in	Threads per inch	Diam at root of thread, in	Area at root of thread, sq in	Diam of screw, in	Threads per inch	Diam at root of thread, in	Area at root of thread, sq in

Nuts and Bolt-Heads are determined by the following rules, which apply to both square and hexagon nuts:

Short diameter of rough nut = 1 1/2 × diam of bolt + 1/8 in.
Short diameter of finished nut = 1 1/2 × diam of bolt + 1/16 in.
Thickness of rough nut = diam of bolt.
Thickness of finished nut = diam of bolt − 1/16 in.
Short diameter of rough head = 1 1/2 × diam of bolt + 1/8 in.
Short diameter of finished head = 1 1/2 × diam of bolt + 1/16 in.
Thickness of rough head = 1/2 short diam of head.
Thickness of finished head = diam of bolt − 1/16 in.

The long diameter of a hexagon nut may be determined by multiplying the short diameter by 1.155, and the long diameter of a square nut by multiplying the short diameter by 1.414.

Standard Dimensions of Nuts and Bolt-Heads

Diam of bolt	Short diam, rough	Short diam, finished	Long diam, rough	Long diam, rough	Thickness, rough. Nut	Thickness, finished. Both	Thickness, rough. Head

For length of shaft required to form rivet-head, see Chapter XII.

NAILS AND SCREWS *

Nails. Based upon the process of manufacture there are three kinds of nails in common use, namely, plate or cut nails, wire nails, and clinch-nails. These are briefly described in the following subdivisions of this article and other data bearing on the subject are included.

(1) **Cut Nails.** Cut nails are made from a strip of rolled iron or steel of the same thickness as the finished nail and a little wider than its length, the fiber of the iron being parallel with the length of the nail. Special machinery cuts the nails out in alternate wedge-shaped slices, the heads are then stamped on them and the finished nails dropped into the casks. Cut nails made from iron are generally preferred for use in exposed positions. Cut nails are made in a variety of shapes to suit special uses. For ordinary use in building, nails of three different shapes are made, and the nails are called COMMON NAILS, FINISH-NAILS and CASING-NAILS. The common nails are used for rough work, finish-nails for finished work, and casing-nails for flooring, matched ceiling and sometimes for pine casings, although the heads are rather too large for finish-work. Cut nails are beginning to return to favor as they have holding power and lasting qualities superior to wire nails.

(2) **Brads.** Brads are thin nails with a small head, used for small finish, panel-moldings, etc. They vary from $\frac{1}{4}$ to 2 in in length.

(3) **Clout-Nails.** Clout-nails are made with broad, flat heads, and are sold in sizes varying from $\frac{3}{8}$ to $2\frac{1}{2}$ in in length. They are used chiefly for fastening gutters and metal-work. Special nails are also made for lathing, slating, shingling, etc.

(4) **Wire Nails.** These have of late years become as common as the cut nails, and are sold at about the same price. They are said to be stronger for driving than the cut nails, not so liable to bend or break, especially when driven into hard woods, and less liable to split the wood; for these reasons they are generally preferred by carpenters. Wire nails are made from wire, of the same section-diameter as the shank of the nail, by a machine which cuts the wire in even lengths, heads and points them, and, when desired, also barbs them. In general, the same classification is used for cut nails. It should be noticed that the gauge of the wire and the shape of the head vary in the different kinds, and that some are barbed, others plain. The various types of wire nails are drawn ROUND, SMOOTH or BARBED, for the domestic trade; for export they are drawn OVAL, SQUARE, or DIAMOND-SHAPED, according to the country to which they are to be shipped and its requirements.

(5) **Clinch-Nails.** These are made from open-hearth or Bessemer-steel wire. Any ordinary wire nail will clinch, especially when made with DUCK-BILL or flattened points for clinching purposes, or even otherwise, if annealed. These nails are used only in places where it is desired to turn over the ends of the nails to form a clinch, as in the case of battens or cleats.

(6) **Length and Weight of Nails.** The length of nails is designated by PENNIES (*d's*). Two explanations are given for the origin of this classification; for example, that tenpenny nails originally sold for tenpence a hundred, or that 1 000 tenpenny nails originally weighed 10 lb. The designation is retained by manufacturers, both for cut and wire nails. The weights expressed in pennies run from two pennies to sixty pennies, the larger sizes being designated by fractions of an inch. The sizes and lengths of various kinds of nails and tacks are given in the following tables.

* Prepared by the late Thomas Nolan.

(7) Sizes of Nails for Different Classes of Work. It is imperative for first-class work that nails of proper size should be used and to insure the best results it is well in certain classes of work to specify the sizes which are to be used. For framing, twentypenny, fortypenny and sixtypenny nails, or spikes, are used, according to the size of the timber. For sheathing and roof-boarding, underfloors and cross-bridging, tenpenny common nails should be used. For over-floors tenpenny floor-nails or casing-nails should be used for jointed boards, and ninepenny or tenpenny for matched flooring, although eightpenny nails are sometimes used. Ceiling when $\frac{3}{4}$ in thick is generally put up with eightpenny casing-nails, and when thinner stuff is used, with sixpenny nails. For inside finish any size of finish-nails or brads from eightpenny down to twopenny is used, according to the thickness and size of the moldings. For pieces exceeding 1 in in thickness, tenpenny nails should be used. Clapboarding is generally put on with sixpenny finish-nails or casing-nails. Threepenny to fourpenny are used for shingling and slating, and threepenny for lathing. For slating, galvanized nails should be used, and they are also better for shingling. Whether wire or cut nails should be used may generally be left to the builder; but in places where there is any danger of the nails being drawn out either by the warping of the boards or from the pull of the nail, cut nails should be used, as they have greater holding power than the wire nails under certain conditions. In regard to the comparative holding power of cut nails and wire nails, and barbed nails and smooth nails, and tests made to determine this property, see tables under (9).

(8) Copper and Brass Nails. Nails are also made of copper and cast brass, and these are sometimes used in connection with boat-building, refrigerator-work, etc. One wing of the Physical Laboratory Building of Harvard College is put together entirely with brass and copper. As the rooms were intended for use in delicate electrical work, no iron was used in their construction.

(9) Cement-coated Wire Nails. The coating consists of various resinous gums mixed by a secret formula, and put on the nails by a baking-process which involves the use of quite complicated machinery. Although the chief market for coated nails is among the users of packages to be shipped, there is a limited market for them among builders, for construction-purposes. The chief merit of the coating is that it gives the nail an adhesive resistance approximately twice that of ordinary wire nails. This quality appeals especially to the manufacturers and users of packages to be shipped, for which strength is particularly wanted. It is desirable for construction-purposes also, but the lack of holding power in plain wire nails is not so apparent in building. About 90% of the output goes to box-factories and large shippers. Cement-coated nails are quite widely used, also, in laying both ordinary and parquetry-flooring. The use of these nails, with a special head which leaves a small hole, gives a firm floor and prevents springing. Though the makers do not claim that the nails are absolutely rust-proof, they do claim that nails thus treated will resist the effects of moisture from 20 to 50% better than the uncoated wire nails. But it is when in use that the non-rusting quality is most evident. There is more coating on the nails than is actually necessary for holding power. The heat caused by the friction of driving the nail softens the coating and the surplus is forced toward the head, completely closing the opening; this prevents the admission of moisture between the wood and the nail. Under similar conditions, the life of a cement-coated nail will be about twice as long as that of an uncoated one. Less force is needed to drive a coated nail as the softened coating forms a lubricant. These nails are made in two types, differing only in the heads, and are either COOLERS or SINKERS. The former

have large flat heads; the latter, heads slightly reinforced by counter-sinking. They are made to replace common nails, in sizes from $\frac{1}{4}$ in to 1 in, and are used for framing, boarding, shingling and staging, and for boxes and crates. Results of tests made with cement-coated nails to determine their adhesive resistance in comparison with the common smooth-wire nails are given below.

The following table shows the result of tests made at the United States Arsenal, Watertown, Mass., in 1902, the wood being pine:

Comparative Adhesive Resistance of Common Smooth-Wire Nails and Cement-Coated Nails

All nails were driven into the same piece and were perpendicular to the grain

Size and name	Diameter, in	Length driven,* in	Adhesive resistance,† lb
Tenpenny, common, smooth.	0.145	$2\frac{1}{2}$	167
Tenpenny, coated	0.117	$2\frac{1}{2}$	418
Ninepenny, common, smooth .	0.132	$2\frac{1}{4}$	182
Ninepenny, coated	0.114	$2\frac{1}{4}$	327
Eightpenny, common, smooth	0.132	2	189
Eightpenny, coated	0.112	2	316
Sixpenny, common, smooth .	0.097	$1\frac{5}{8}$	106
Sixpenny, coated . .	0.092	$1\frac{5}{8}$	226

* All of the nails were left with their heads projecting from $\frac{1}{4}$ to $\frac{1}{2}$ in.

† Average of three trials.

Holding Power of Nails. A committee appointed by the Wheeling nail-manufacturers, a number of years ago, to test the comparative holding power of cut and wire nails. published the following data. The kind of wood is not named. The effect of barbs is slight, and definite conclusions await complete tests.

Pounds Required to Pull Nails Out

	Cut	Wire		Cut	Wire
Twentypenny	1 593	703	Sixpenny .	383	200
Tenpenny ..	908	315	Fourpenny . .	286	123
Eightpenny	597	227			

The holding power of nails varies with the kind of wood into which they are driven. Austin T. Byrne gives the relative holding power of woods as ABOUT as follows: White pine, 1; yellow pine, 1.5; white oak, 3; chestnut, 1.6; beech, 3.2; sycamore, 2; elm, 2; basswood, 1.2.

Comparative Holding Power of Cut and Wire Nails

Very thorough tests of the comparative holding power of wire nails and cut nails OF EQUAL LENGTHS AND WEIGHTS were made at the U. S. Arsenal in 1892 and 1893. From forty series, comprising forty sizes of nails driven in spruce wood, it was found that the cut nails showed an average superiority of 60.50%, the common nails showing an average superiority of 47.51% and the finishing-nails an average of 72.22%. In eighteen series, comprising six sizes of BOX-NAILS driven into pine wood, in three ways the cut nails showed an average superiority of 99.93%. In no series of tests did the wire nails hold as much as the cut nails.

Quantity of Nails Required for Different Kinds of Work

For 1 000 shingles* allow 3½ to 6½ lb fourpenny nails or 3½ to 4½ lb threepenny
- 1 000 laths, 7 lb threepenny fine, or for 100 sq yd of lathing, 10 lb threepenny fine
- 1 000 sq ft of beveled siding, 18 lb sixpenny
- 1 000 sq ft of sheathing, 20 lb eightpenny or 25 lb tenpenny
- 1 000 sq ft of flooring, 30 lb eightpenny or 40 lb tenpenny
- 1 000 sq ft of studding, 15 lb tenpenny and 5 lb twentypenny
- 1 000 sq ft of 1 by 2½-in furring, 12-in centers, 9 lb eightpenny or 14 lb tenpenny
- 1 000 sq ft of 1 by 2½-in furring, 16-in centers, 7 lb eightpenny or 10 lb tenpenny

* Depends upon width and length of shingles and kind of nails.

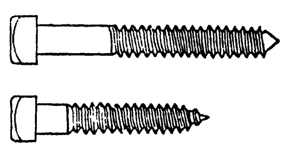
3	⅜	5 333	12	¾	1 333	22	1 1/16	727
..	.			.	.	24	1⅛	666

Wire carpet-tacks are made polished, blued, tinned, or coppered, there are also upholsterers' and bill-posters' or railroad tacks.

Expansion-bolt

Expansion-Bolts. These are commonly used for bolting wood or iron to masonry that is already built. A hole is drilled in the masonry of such size that the expansion-nut will fit closely, and when the bolt is screwed up the nut expands and binds firmly in the masonry. The illustration shows the Evans expansion-bolt, which is also furnished with screw-head bolts. There are other forms of expansion-bolts on the market. From experiments on expansion-bolts it was found that the holding capacity was 264 lb per sq in when embedded in 1:2 Portland-cement mortar, 843 per sq in when embedded in sulphur and 485 lb per sq in when embedded in lead. For average working unit-stresses it is safe to use about one-fifth of the values given. When the work is exposed to rain or moisture sulphur should not be used as the acid which results will rust the metal and will also tend to disintegrate the masonwork at the point of entrance of the bolt.

Screws. The substitution of screws for nails in building operations is a marked feature of modern work. Trimming hardware of all descriptions is put on with screws, and a great deal of panel-work, inside finish, etc , is put together with them. Stop-beads, the casings of plumbing-fixtures, etc., should be fastened with screws, as well as all kinds of store and office-fixtures, and cabinet-work in general, except where the joints are glued. Screws are also largely used in making furniture. They present a neater appearance than nails, have greater holding power and are less apt to injure the material if it should be removed and replaced. By making holes for the screws with a bit, all danger of splitting the finish is averted. The ordinary type of screw has a gimlet-point by which it can be turned into the wood without the aid of a bit. The heads are made in various forms to suit different uses. Screws are made ordinarily of steel, but sometimes of brass and bronze. The latter sort are used for screwing in place finished hardware of the same material, and have heads finished to correspond with the trimmings. Steel screws, also, are finished with blue, bronze, lacquered, galvanized, or tinned surface, to match the cheaper class of trimmings. The galvanized finish is used in building operations at the seashore. Screws with blue surface, called BLUED SCREWS, are generally used with japanned hardware and for stop-beads, and wherever a cheap round-headed screw is desired. Silver, nickel, and gold-plated screws are also manufactured for use in connection with similar hardware. Steel screws for wood are made in twenty different lengths, varying from ¼ to 6 in, and each length of screw has from six to eighteen varieties in thickness, there being in all thirty-one different gauges; so that altogether there are in the market about two hundred and fifty different sizes of ordinary screws used for woodwork. The most common shapes are the ordinary flat head, round head and oval head. The oval-head screw is tapered for countersinking but is slightly rounded on top



Lag and Coach-screws

Patent diamond-point steel screws are made especially for driving with a hammer. These can be driven with a hammer their entire length into any hard wood, and then held by one or two turns as securely as the ordinary screw. In ordering screws both the length and number of the gauge or diameter of the shank, the material and finish, and the use to which they are to be put, should be given

Screws for Metal have the same diameter throughout and the threads are V-shaped.

Sizes of Screws. The sizes of screws are given in length in inches and the number of the gauge, the gauge denoting the diameter. Thus, a 1-in No. 12 screw is 1 in long and 0.2158 in in diameter. The gauge-numbers range from 0 to 30 and the lengths from ¼ to 6 in. The lengths vary by eighths of an inch up to 1 in, by quarters of an inch up to 3 in and by halves of an inch up to 5 in. Screws from ⅝ to 4½ in long are made in about sixteen different gauge-numbers. Table XIII, Chapter XI, gives the diameter to four places in decimals of an inch of the American screw-gauge. It should be noticed that, unlike the ordinary wire-gauges, the 0 of the screw-gauge indicates the diameter of the smallest screw while the diameter of the screw increases with the number of the gauge.

Lag-Screws and Coach-Screws are large, heavy screws used where great strength is required, as in heavy framing, and for fixing ironwork to timber. Lag-screws with conical point are made with diameters of 5/16, ⅜, 7/16, ½, 9/16,

⅝, ¾, and 1 in, and in lengths from 1½ to 12 in; coach-screws in diameters from 5/16 to ¾ in and in lengths from 1½ to 12 in. For putting in lag-screws a hole should be bored which has a diameter a little greater than the unthreaded shank of the screw and it should be bored to a depth corresponding to the length of the unthreaded shank. A second hole should then be bored at the bottom of the first hole of a diameter somewhat less than that of the threaded shank and to a depth of about half its length.

Holding Power of Lag-Screws

Kind of wood	Size of screw, in	Size of hole bored, in	Length in wood, in	Maximum resistance, lb	Number of tests
Seasoned white oak.	⅝	½	4½	8 037	3
Seasoned white oak.	9/16	7/16	3	6 480	1
Seasoned white oak.	½	⅜	4½	8 780	2
Yellow-pine stick	⅝	½	4	3 800	2
White cedar, unseasoned	⅝	½	4	3 405	2

Hoopes & Townsend give the force required to draw screws out of yellow pine as follows:

Screw...	½ in	⅝ in	¾ in	⅞ in	1 in
Wood, depth...	3½ in	4 in	4 in	5 in	6 in
Force, pounds...	4 960	6 000	7 685	11 500	12 620

Wooden-screws are sold by the gross, lag-screws and coach-screws by the pound.

DATA ON EXCAVATING

Excavating is almost invariably measured by the cubic yard of 27 cu ft. For measuring excavations of irregular depth see Part I. For computing the contents of wells and cesspools, the circular area in square feet may be obtained from the table of Areas and Circumferences, Part I, and this circular area multiplied by the depth in feet will give the contents in cubic feet. The cost of excavating and removing earth is ordinarily made up of the following items:

(1) Loosening the earth for the shovelers;
(2) Loading by shovels into carts or barrows:
(3) Hauling or wheeling it away, including emptying and returning;
(4) Spreading it out on the dump;

For every large job, such as railroad-work, it is also necessary to make an allowance for keeping the hauling-road in repair, for sharpening and repair of tools, and for carts, harness, superintendence and water-carriers. Where the dirt excavated can be spread over the ground immediately surrounding the excavation the loosened dirt may be removed by scrapers without shoveling. Today, practically all excavations are made by mechanically operated shovels, steam, gasoline or electric; hauling is performed by trucks or tractors.

Data for Estimating Cost of Loosening Earth. Two men with a plough and team of horses will loosen from 20 to 30 cu yd of strong, heavy soil per hour or

from 40 to 60 cu yd of ordinary loam. One man with a pick will loosen 1⅛ yd per hour of stiff clay or cemented gravel, 4 yd of common loam, or 6 yd of light sand.

The average quantity of LOOSENED EARTH that a man can shovel into a cart per hour is:

Loam or sand	2.0 cu yd
Clay and heavy soils	1.7 cu yd
Rock	1.0 cu yd

Average earth when loosened swells to from 1⅕ to 1⅓ times its original bulk in place.

The capacity of vehicles used for moving excavated materials is about as follows:

Wheelbarrows	3 to 4 cu ft
One-horse dump-carts	18 to 22 cu ft
Two-horse dump-wagons	27 to 45 cu ft*
Drag-scrapers	3 to 7 cu ft
Wheel-scrapers	10 to 17 cu ft
Dump-cars on rails	27 to 80 cu ft
Steam shovels	¾ cu yd
Motor trucks	1 to 5 tons

The Economical Length of Haul with drag-scrapers is about 150 ft; with wheeled scrapers, 500 ft; with wheelbarrows, 250 ft; with one-horse dump-carts, 600 ft.† The average speed of horses is given as about 200 ft per minute.

Weight of Earth, Sand and Gravel. For general calculations the following average values may be taken:

14 cu ft of chalk weigh 1 ton	19 cu ft of gravel weigh 1 ton
18 cu ft of clay weigh 1 ton	22 cu ft of sand weigh 1 ton
21 cu ft of earth weigh 1 ton	

Rock-Excavation. A cubic yard of rock, in place, when broken up by blasting for removal by wheelbarrows or carts, will occupy a space of about 1⅗ cu yd; consequently, the cost of hauling or removal is about 50% more than for dirt.

DATA ON STONEWORK

Kinds of Stonework. The commonest kind of stonework, that is, for walls, is called RUBBLEWORK. No work whatever is done on the stones except to break them up with a hammer. If the wall is built in courses it is designated COURSED RUBBLE. When the stones showing on the outside face of the wall are squared, the work is designated ASHLAR. Ashlar is of two kinds: COURSED ASHLAR, in which the stones are laid to form courses around the building, all of the stones in any course being of the same height, and BROKEN ASHLAR, in which stones of different heights are used. HAMMER-DRESSED ASHLAR designates work where the stones are roughly squared with a hammer. This is a very cheap class of work. Good ashlar work should be squared on the bench with chisels, and with beds and end-joints cut square to the face. Stonework

* The ordinary load for two-horse wagons such as are commonly used for hauling dirt sand and gravel is from 1¼ to 1½ cu yd

† Inspectors' Pocket-Book, by A. T. Byrne.

which requires a chisel or any other tool except a hammer for dressing is called CUT WORK. Cut work costs considerably more than hammer-dressed work.

Measurement of Stonework. Rough stone from the quarry is usually sold under two classifications: rubble-stone and dimension-stone. Rubble includes the pieces of irregular size most easily obtained from the quarry, and suitable for cutting into ashlar 12 in or less in height and about 2 ft long. Stone ordered to be of a certain size, to SQUARE over 24 in each way and to be of a particular thickness, is called DIMENSION-STONE. The price of the latter varies from two to four times the price of RUBBLE. Rubble is generally sold by the ton or carload. Footings and flagging are usually sold by the square foot; dimension-stone by the cubic foot. In Boston, granite blocks for foundations are usually sold by the ton.

In Estimating on the Cost of Stonework put into a building, the custom varies with different localities, and even among contractors in the same city. Dimension-stone footings, that is, squared stones 2 ft or more in width, are usually measured by the square foot. If built of large rubble or irregular stones the footings are measured in with the wall, allowance being made for the projections of the footings. Rubblework is almost universally measured by the PERCH of $16\frac{1}{2}$ cu ft. In Philadelphia, St. Louis and some sections of Illinois, 22 cu ft are called a perch. Railroad-work is usually measured by the cubic yard. When stonework is let by the perch, the number of cubic feet to the perch should be stated in the contract, and it should be stated, also, whether or not openings are to be deducted. As a rule no deductions are made for openings of less than 70 superficial feet.

Data for Estimating Cost. A ton of most of the different kinds of stones will make from 1 perch to $1\frac{1}{4}$ perches.

The cost of laying one perch of stone may be estimated by the following items:

Labor: mason $2\frac{3}{8}$ hrs, helper $1\frac{2}{3}$ hrs, based on two helpers to three masons; sand $\frac{1}{5}$ load; lime $\frac{3}{4}$ bu, or if laid in all-cement mortar, one perch will require from $\frac{1}{3}$ to $\frac{1}{2}$ bbl of cement.

DATA ON BRICKS AND BRICKWORK *

Definition of Brick. The American Ceramic Society † defines brick as "A structural unit in the form of a rectangular prism (usually solid and $8 \times 3\frac{3}{4} \times 2\frac{1}{4}$ in in size). In the present state of the art the term 'brick,' when used without a qualifying adjective, is generally understood to mean a structural unit of clay or shale formed while plastic and subsequently fired. When substances other than clay or shale are employed, such as lime and sand, cement and sand, fire-clay, adobe, etc., the term 'brick' should be suitably qualified."

Manufacturing Methods. Manufacturing processes, while varied in character, consist essentially of screening, grinding and working the clay to the desired consistency for molding, whether by hand or machine. After molding the brick are dried and then burned in kilns for many hours at high temperatures, approximately 2 000° F. These processes tend to purify the raw prod-

* Much of the material in this section is compiled from data furnished by the Common Brick Manufacturers' Association of America.

† Journal American Ceramic Society, Vol. II, No. 6, June, 1928.

uct, make it uniform and homogeneous, burn out all combustible matter and result in a product which is both chemically stable and physically permanent.

Trade Names. Trade names are derived from the methods of manufacture. Placing soft mud in molds is known as the SOFT-MUD process. Forcing the clay from the orifice of an augur or extrusion machine in a continuous column and then cutting brick of the column is called the stiff-mud process. Molding relatively dry clay under high pressure is the DRY-PRESS method. Brick are SAND-MOLDED if the molds are coated with sand to facilitate the removal of the brick. If the molds are wetted for the same purpose the brick are WATER-STRUCK. Brick made in the extrusion machines are END-CUT or SIDE-CUT according to the face that is cut as the molded column leaves the machine.

Appearance of Brick. The character of clay, or mixtures of clays and shales, the manner of molding or forming, the manner and degree of burning, all influence the appearance of the brick. The whole sweep of color, in smooth to rough textures, is available, from the severe tones of pearl grays or creams, through buff, golden and bronze tints of the descending scale of reds, down to purples, maroons, and even gun-metal blacks. All of the foregoing applies to what are known as COMMON BRICK, which are used for all purposes, including facing. Some demands and usage have led to the controlled production of specific surface treatments, and bricks so specially processed and used in exposed masonry surfaces go by the trade name of FACE-BRICK.

Size and Weight of Brick. In the United States the American Society for Testing Materials has standardized the size of building brick as follows: "The standard sizes shall conform to the following dimensions, with a permissible variation, plus or minus, of $\frac{1}{16}$ in in depth, $\frac{1}{8}$ in in width and $\frac{1}{4}$ in in length." While there are still some departures from these standards, and while, in the opinion of some, changes therefrom are desirable, the majority of manufacturers now conform to them. Specific gravity of building brick ranges from approximately 1.57 for medium-burned, dry-press surface clay brick to 2.32 for very hard-burned stiff-mud shale brick.

Type	Depth, in	Width, in	Length, in
Common brick	$2\frac{1}{4}$	$3\frac{8}{4}$	8
Rough-face brick	$2\frac{1}{4}$	$3\frac{3}{4}$	8
Smooth-face brick	$2\frac{1}{4}$	$3\frac{7}{8}$	8

Classification. There is a very considerable range in the compressive strength of brick, owing to variations in raw materials, methods of manufacture and degree of burning. The examination of tests of several thousand brick indicates, for instance, an average minimum compressive strength of 1 659 lb per sq in and an average maximum of 22 500 lb per sq in. It is probably a safe assertion that more than 75 per cent of all brick now manufactured in the United States have an average compressive strength of more than 3 000 lb per sq in. In its standard specifications for building brick (A.S.T.M. Designation: C 62–29), the American Society for Testing Materials has established the following classification: *

* The classifications are based on strength and do not necessarily measure weather-resistance.

Name of grade	Compressive strength (bricks flatwise), lb per sq in		Modulus of rupture (bricks flatwise), lb per sq in	
	Mean of five tests	Individual minimum	Mean of five tests	Individual minimum
Grade A... .	4 500 or over	3 500	600 or over	400
Grade B	2 500–4 500	2 000	450 or over	300
Grade C....	1 250–2 500	1 000	300 or over	200

The U. S. Government Master Specifications make use of another classification based upon transverse breaking load and absorption characteristics, as follows:

Physical Requirements

Class	Absorption, per cent		Transverse breaking load, lb, 7-in span	
	Average of five	Individual maximum	Average of five	Individual minimum
V.......	5 or less	6	2 170 or more	1 450
H....	5 to 12	15	1 080 or more	725
M	12 to 24	28	810 or more	540
S................	24 or more	No limit	540 or more	360

It is now seriously questioned by investigators,* however, that the water-absorption of building brick is a measure of its durability or tendency to transmit water.

Fire-Bricks are ordinarily made from a mixture of flint clay and plastic clay. They are usually white, or white mixed with brown, in color and are used for the lining of furnaces, fireplaces and tall chimneys.

Paving Brick. Paving brick are very hard brick, usually annealed. They are seldom used in building. The American Society for Testing Materials has included the following in its Tentative Specifications for Paving Brick (A.S.T.M. Designation: C 7–29T):

NOTE. The sizes and varieties recognized by the Permanent Committee on simplification of Varieties and Standards for Vitrified Paving Brick of the U. S. Department of Commerce given below are recommended for use whereever practicable:

	Depth, in	Width, in	Length, in
Plain wire-cut (vertical fiber lugless as usually laid). ...	2½	4	8½
	3	4	8½
	3½	4	8½
Wire-cut lug (Dunn).........	3	3½	8½
	4	3½	8½
Repressed lug................	4	3½	8½

* Report of Committee C-3 on Brick for 1928, Proc. Am. Soc. Test. Mat. 28 (2): 306–10 (1928).
H. Kreuger, Investigations of Climatic Actions on the Exterior of Buildings.
J. W. McBurney, Water Absorption and Penetrability of Brick, Proc. Am. Soc. Test Mat. 29 (2): 711–30 (1929).

The above sizes and varieties are those recognized by the Permanent Committee for the year 1929, and are subject to change from year to year.

Lime-Mortar Bricks. General Description. SAND-LIME BRICKS were originally made of lime mortar, molded in brick form and hardened by exposure to the air. Such bricks are said to have been largely used in ancient times, and it is claimed that remains of such materials are now in evidence and in a good state of preservation. It is known that they were formerly used in Europe in localities where other materials were not readily available, and that they have been used in some localities in this country during the past thirty-five years. The writer knows of several houses in Haddonfield, N. J., built of such bricks, generally with the exterior surfaces plastered. One of them, however, said to be about twenty-five years old, has not been plastered, and an inspection (1915) shows the bricks to be in an excellent state of preservation. Lime-mortar bricks harden by the absorption of carbonic-acid gas from the air. This gas enters into combination with the lime, forming carbonate of lime. The hardening process requires several weeks' exposure under cover and the product has not virtues sufficient to commend it where other materials are available.

Sand-Lime Bricks. It was discovered in Germany about 1875 that lime-mortar bricks could be hardened in a few hours under heat and pressure, and it was found later that the chemical reaction under the new process differs essentially from that just described, and that the percentage of lime can be greatly reduced. Sand-lime bricks were first made in Germany about 1880, and the more extended commercial development of the industry dates back in Europe to about 1888, and in this country, to about 1900.

Manufacture of Sand-Lime Bricks. Pure silica sand, mixed with from 5 to 10% of high-calcium lime and a certain proportion of water, is molded under very high pressure into the form of bricks. These are piled loosely on cars holding about 1 000 bricks each and placed in a steel cylinder large enough to hold from 10 to 20 cars The cylinder is then closed and steam is turned in and maintained at a pressure of from 120 to 135 lb to the square inch for from 8 to 10 hours, when the cylinder is opened and the bricks removed, ready for use. The tremendous pressure, which is said to be 100 tons on each brick, under which the bricks are formed, causes great density and a bringing of the component elements into close contact. The heat in the cylinder dries the bricks and causes a chemical reaction between the lime and a portion of the silica, forming a hydrosilicate of lime, an insoluble and durable element, which bonds the remaining particles of the sand together and forms a comparatively strong cementing material. The small residue of uncombined lime combines, in the course of time, either with silica or with carbonic-acid gas from the air, until no free lime remains. The bricks thus become harder and stronger with age. In regard to the constitution of sand-lime bricks, Edwin C. Eckel says. "It may be safely assumed that a sand-lime brick as marketed consists of (1) sand-grains held together by a network of (2) hydrous lime silicate, with probably (if a magnesian lime is used) some allied magnesium silicate, and (3) lime hydrate or a mixture of lime and magnesia hydrates. These three elements will always be present, and the structural value of the brick will depend in large part on the relative percentage in which the sand and the hydrates occur."

Quality of Sand-Lime Bricks. The quality of the product depends mainly upon the selection and treatment of the sand and the lime. Pure silica sands,

containing a large percentage of fine grains passing through screens of from 80 to 150 mesh, are preferable. Clay or kaolin are dangerous elements and should not be present in quantities of more than 5%. The lime should be, preferably, high-calcium lime, the magnesium silicates formed by impure limes not being as strong as calcium silicates. Some manufacturers use ready-hydrated lime, others hydrate the lime themselves, before mixing it with the sand, and others grind the quicklime, mix it with the sand and slake it in the sand. The other most important element affecting quality is the press. After pressing and before steaming, the bricks are very fragile and the press should be such that they are subjected to no shaking or friction after the pressure is removed from the mold. Vertical clay-brick presses have been commonly used, but do not appear to be well adapted to the purpose. The rotary table-presses seem to be most successful.

Tests of Sand-Lime Bricks. If the sand is reasonably clean and pure, and the lime finely divided, and if the bricks are sound and have a good metallic ring, they will stand weather-exposure well. If a brick stands in still water for an hour and the moisture rises more than ½ in, it is not a first-class brick; if the moisture rises 2 in, its use for facings is questionable; and if the moisture rises 3 in, it should not be used on outside work of any importance. Authentic tests have been made for crushing, fire-resistance, frost-resistance, acid-resistance and absorption, from which it may be concluded that under proper conditions of manufacture sand-lime bricks are produced having the following physical characteristics: Crushing strength, average, between 2 500 and 3 000 lb per sq in, although some specimens have shown over 5 000 lb per sq in; modulus of rupture, average, about 450 lb per sq in; fire-resistance, but little inferior to that of fire-brick; frost-resistance, generally good, acid-resistance, superior; absorption, from 7 to 10% in 48 hours; rate of absorption, slower than for clay bricks; average absorption for complete saturation, 14%; reduction of compressive strength by saturation for absorption-test, average 33%.

Special Properties of Sand-Lime Bricks. The bricks are square, straight, uniform in size and homogeneous in composition and density. They cleave accurately under the stroke of the trowel and present a weather-surface with the good qualities of stone. They can be cut, carved or sand-blasted, are easily washed clean and show no efflorescence. These claims are well established for properly manufactured sand-lime bricks. It should be further stated that common bricks and facings are made in the same press, the only difference being in the selection of the materials and in the handling of the raw bricks. It is therefore claimed that a rational and homogeneous exterior wall-structure is possible, since backings and facings may be built and bonded in even courses, with Flemish or other ornamental bonds. Some factories, however, manufactured, at first, inferior bricks and care should still be taken in selections from their outputs. Frequently, the ordinary runs of sand-lime bricks are not as strong as the average clay building bricks and some of them are too low in their resistance to frost.

Colors of Sand-Lime Bricks. The natural color is pearl-gray, varying in warmth with the composition of the sand. Permanent colors are produced by introducing mineral oxides with the raw materials in quantities varying according to the intensity of color desired; but as the oxides are foreign materials in the bricks, they affect the quality of the latter in proportion to the quantity used.

Glazed and Enameled Bricks. The terms GLAZED BRICKS AND ENAMELED BRICKS as commonly used, refer practically to the same product, and neither includes what is known as SALT-GLAZED BRICK. The enameled or glazed bricks are generally dipped or sprayed and then burned, whereas the salt-glaze is obtained by the introduction of salt into the fire-boxes of kilns while the bricks are being burned. Glazed or enameled bricks are generally divided into two classes: (1) true enameled bricks, which have a glaze containing the coloring matter applied to it without any intermediate SLIP; (2) bricks which have a transparent glaze placed over a white or colored slip, the slip coming between the glaze and the material to be glazed. The latter is the process most used in this country. Manufacturers differ as to which process produces the best bricks although it would seem as though the true enamel would not chip or peel as readily. These bricks can be made in a variety of colors, from white to dark green or chocolate, and either in a HIGHLY GLAZED FINISH or in a DULL, SATIN-FINISH, the latter finish being quite desirable in many instances on account of its doing away with the glare of the more highly glazed bricks or tiles. An enameled surface may be distinguished from a glazed surface by chipping off a piece of the brick. The glazed brick will show the layer of slip between the glaze and the body of the brick; while the enameled brick will show no line of demarcation between the body of the brick and the enamel. American enameled and glazed bricks are now extensively used for the exterior surfaces of buildings, particularly for street-fronts and light-courts, and for interior side walls and partitions of rooms or buildings used for a great variety of purposes.

Sizes of Enameled Bricks. Enameled bricks are made in two regular sizes: (1) English size, 9 by 3-in enameled surface, $4\frac{1}{2}$-in bed, and (2) American size, $8\frac{3}{8}$ by $2\frac{1}{4}$-in enameled surface, $4\frac{1}{8}$-in bed. The English-size bricks cost more than the American, but on account of the saving in the number of bricks, labor of laying and mortar in joints, the former effect a saving. Enameled bricks are made, also, with a 12 by $4\frac{1}{8}$-in enameled surface, $2\frac{1}{4}$-in bed.

Colors of Enameled Bricks. The standard colors carried in stock are white, cream, buff, black, blue, green, etc.

Estimating Quantities of Brickwork

Methods of Calculation. With the adoption of standard sizes for brick the former practice of "rule of thumb" calculations is rapidly giving way to accurate methods of determining quantities of materials and labor, which with unit costs known for a given locality, result in dependable estimates.

Measurements. Surface areas of walls are determined, making deductions for all openings. Dimensions of foundations, piers and chimneys are also essential. With this information in hand, the following tables may be used to advantage. These tables are conservative in so far as labor is concerned and are based upon that required for carefully faced exterior work. For rougher work, the amount of labor required may be reduced, while for intricate work of any character, an increase will be necessary.

Brick Masonry. Materials and Labor Required for 1 000 sq ft Wall—½-in Joints

Materials Required for Mortar. The following quantities of materials are required for 1 000 cu ft of mortar, lump lime in 180-lb barrels, hydrated lime in 50-lb sacks, cement in 94-lb sacks: Lime mortar, 1 : 2½—57 bbl, lump lime or 350 sacks of hydrated lime and 37 cu yd of sand; lime mortar, 1 : 3—47 bbl of lump lime or 292 sacks of hydrated lime and 37 cu yd of sand; cement-lime mortar, 1 : 1 : 6—130 sacks cement, 24 bbl lump lime or 146 sacks hydrated lime and 37 cu yd sand; cement mortar, 1 : 2—442 sacks cement, 16 bbl lump lime or 92 sacks hydrated lime and 34 cu yd sand; cement mortar, 1 : 3—331 sacks cement, 12 bbl lump lime or 69 sacks hydrated lime and 39 cu yd sand; cement mortar, 1 : 4—264 sacks cement, 10 bbl lump lime or 55 sacks hydrated lime and 41 cu yd sand. NOTE: Cement mortars have 10% of the cement content, by weight, replaced with lime.

LIME *

Nature and Properties of Lime. Chemically, lime is calcium oxide. Used in a broader sense, it is the class-name of a great variety of products manufactured by the calcination of LIMESTONE. Limestone consists of the carbonates of calcium and magnesium which vary widely in their ratio to each other. The limestones used in the manufacture of lime products may be

* **Valuable practical data relating to lime and plaster have been furnished by the Charles Warner Company, of Wilmington, Del.**

divided into two classes, CALCIUM LIMESTONES and DOLOMITIC LIMESTONES. High-calcium limestones contain only a relatively low percentage of magnesium carbonate, while dolomitic limestones contain a considerable amount of it. Dolomitic limestone usually corresponds roughly to the theoretical formula of dolomite ($CaCO_3$) ($MgCO_3$). The CALCINATION of limestone consists of heating to expel the carbon dioxide. The product resulting from calcination of limestone is known as QUICKLIME and possesses great affinity for water. SLAKING is the process of adding water to quicklime. During the process of slaking, heat is energetically evolved and much of the water driven off in the form of steam. During this slaking process, also, high-calcium quicklimes must be agitated and stirred continually or a portion will fail to receive the proper quantity of water and will contain unslaked particles which are likely to slake after being used in the work, causing POPPING, PITTING and disintegration. Dolomitic limes do not slake so energetically, and while they should be stirred while slaking, this is not so necessary as with high-calcium limes. Either class of quicklime, through faulty manufacture, is likely to contain over-burned portions which slake with difficulty and may cause popping, etc., if the lime-paste is not carefully screened before use. The SETTING and HARDENING of common lime mortar is due, first, to the drying out and secondly, to the absorption of carbon dioxide from the atmosphere and the formation of crystals of calcium carbonate to which the strength of the mortar is ascribed. In the manufacture and use of common lime mortar, therefore, the raw material, limestone, is first calcined, and the carbon dioxide expelled; it is then slaked with water and forms calcium hydroxide, in which the water is gradually replaced by carbon dioxide. The lime thus eventually returns to its original carbonate form. As far as the ultimate result is concerned, there is generally little difference between high-calcium and dolomitic quicklimes. Owing to greater familiarity with one or the other of the classes of lime, architects and builders in certain sections of the country prefer one to the other.

Specifications for Quicklime. The lime industry has been made the subject of careful study and the following clauses give the various requirements of Standard Specifications for Quicklime adopted by the American Society for Testing Materials.

1. DEFINITION. Quicklime is a material the major part of which is calcium oxide or calcium and magnesium oxides, which will slake on the addition of water.

2. GRADES. Quicklime is divided into two grades:

(*a*) Selected. Shall be well-burned, picked free from ashes, core, clinker or other foreign material.

(*b*) Run-of-Kiln. Shall be well-burned, without selection.

3. FORMS. Quicklime is shipped in two forms:

(*a*) Lump. Shall be kiln-size.

(*b*) Pulverized Lime. Lump lime reduced in size to pass a ¼-in screen.

4. CLASSES. Quicklime is divided into four classes: (*a*) High-Calcium; (*b*) Calcium; (*c*) Magnesian; (*d*) High-Magnesian.

5. BASIS OF PURCHASE. The particular grade, form and class of quicklime desired shall be specified in advance by the purchaser.

I. Chemical Properties and Tests

(A) Sampling

6. LIME IN BULK. When quicklime is shipped in bulk, the sample shall be so taken that it will represent an average of all parts of the shipment from top to bottom, and shall not contain a disproportionate share of the top and bot-

tom layers, which are most subject to changes. The samples shall comprise at least 10 shovelfuls taken from different parts of the shipment. The total sample taken shall weigh at least 100 lb and shall be crushed to pass a 1-in ring and quartered to provide a 15-lb sample for the laboratory.

7. LIME IN BARRELS. When quicklime is shipped in barrels, at least 3% of the number of barrels shall be sampled. They shall be taken from various parts of the shipment, dumped, mixed and sampled as specified in Section 6.

8. LABORATORY SAMPLES. All samples to be sent to the laboratory shall be immediately transferred to an air-tight container in which the unused portion shall be stored till the quicklime is finally accepted or rejected by purchaser.

(B) Chemical Tests

9. CHEMICAL PROPERTIES. (*a*) The classes and chemical properties of quicklime shall be determined by standard methods of chemical analysis. (*b*) Samples shall be taken as specified in Sections 6, 7 and 8. (*c*) Quicklime shall conform to the following requirements as to chemical composition:

CHEMICAL COMPOSITION

Properties considered	High-calcium		Calcium		Magnesium		High-magnesium	
	Selected	Run of kiln	Selected	Run of kiln	Selected	Run of kiln	Selected	Run of kiln
Calcium oxide, per cent..	90 (min)	90 (min)	85–90	85–90			.	. . .
Magnesium oxide, per cent...	.		.		10–25	10–25	25 (min)	25 (min)
Calcium oxide plus magnesium oxide, min, per cent.	90	85	90	85	90	85	90	85
Carbon dioxide, max, per cent	3	5	3	5	3	5	3	5
Silica plus alumina plus oxide of iron, max, per cent	5	7.5	5	7.5	5	7.5	5	7.5

II. Physical Properties and Tests

10. PERCENTAGE OF WASTE. An average 5-lb sample shall be put into a box and slaked by an experienced operator with sufficient water to produce the maximum quantity of lime putty, care being taken to avoid burning or drowning the lime. It shall be allowed to stand for 24 hours and then washed through a 20-mesh sieve by a stream of water having a moderate pressure. No material shall be rubbed through the screens. Not over 3% of the weight of the selected quicklime nor over 5% of the weight of the run-of-kiln quicklime shall be retained on the sieve. The sample of lump lime taken for this test shall be broken so that all of it will pass a 1-in screen and be retained on a ¼-in screen. Pulverized lime shall be tested as received.

III. Inspection and Rejection

11. INSPECTION. (*a*) All quicklime shall be subject to inspection.

(*b*) The quicklime may be inspected either at the place of manufacture or the point of delivery, as arranged at time of purchase.

(*c*) The inspector representing the purchaser shall have free entry, at all times while work on the contract of the purchaser is being performed, to all parts of the manufacturer's works which concern the manufacture of the quicklime ordered. The manufacturer shall afford the inspector all reasonable facilities for inspection and sampling, which shall be so conducted as not to interfere unnecessarily with the operation of the works.

(*d*) The purchaser may make the tests to govern the acceptance or rejection of the quicklime in his own laboratory or elsewhere. Such tests, however, shall be made at the expense of the purchaser.

12. REJECTION Unless otherwise specified, any rejection based on failure to pass tests prescribed in accordance with these specifications shall be reported within five days from the taking of samples.

13. REHEARING. Samples which represent rejected quicklime, shall be preserved in air-tight containers for five days from the date of the test-report. In case of dissatisfaction with the results of the tests, the manufacturer may make claim for a rehearing within that time.

Hydrated Lime. The slaking of quicklime is an operation which is almost invariably carried on by laborers who have little or no conception of the importance of their task. As a result, many failures have been charged to lime in the past which actually were due to improper preparation during the slaking operation. The new product known as HYDRATED LIME has been offered widely to the trade in recent years and has met with much success. Hydrated lime is a dry flocculent powder resulting from the slaking of quicklime by mechanical means, with an amount of water which is sufficient to satisfy the calcium oxide, but insufficient to make a paste or putty. Hydrated lime is manufactured in mechanical hydrators in which the batches of quicklime and water used are carefully proportioned by weight. After passing from the hydrator, hydrated lime is subjected to a mechanical system of separation which eliminates the coarse or impure particles which may cause popping, etc. Hydrated lime is sold in bags of definite weight and requires only to be mixed with sand and water to make the mortar. The bags have usually been made of heavy burlap or duck cloth, containing 100 lb, or of paper, containing 40 lb. Several of the more prominent manufacturers of hydrated lime in the United States employ chemists who regularly superintend the manufacture of hydrated lime, just as the chemists in Portland-cement factories superintend the proportioning of the raw mix going to the kilns to be burned for Portland cement. The hydrated lime manufactured under such chemical supervision is a reliable product free from tendencies which might give rise to popping, pitting or disintegration. Hydrated lime of good quality may be used for almost any purpose for which lime mortar is used, and is by some considered a more reliable product than quicklime. Among the newer uses for hydrated lime may be mentioned its employment in cement mortars and concrete. An addition of about 15% of hydrated lime to cement mortar or concrete decreases its permeability to water, reduces the cracking due to shrinkage, etc., and increases the plasticity of the mortar or concrete, thus preventing separation of the sand, stone and cement and causing the mixture to flow and fill the forms more readily.

Specifications for Hydrated Lime. The following clauses give the various

requirements of Standard Specifications for Hydrated Lime adopted by the American Society for Testing Materials.

1. DEFINITION. Hydrated lime is a dry flocculent powder resulting from the hydration of quicklime.

2. CLASSES. Hydrated lime is commercially divided into four classes: (*a*) High-Calcium; (*b*) Calcium; (*c*) Magnesian; (*d*) High-Magnesian.

3. BASIS OF PURCHASE. The particular type of hydrated lime desired shall be specified in advance of purchase.

I. Chemical Properties and Tests

4. SAMPLING. The sample shall be a fair average of the shipment. Three per cent of the packages shall be sampled. The sample shall be taken from the surface to the center of the package. A 2-lb sample to be sent to the laboratory shall immediately be transferred to an air-tight container, in which the unused portion shall be stored until the hydrated lime has been finally accepted or rejected by the purchaser.

5. CHEMICAL PROPERTIES (*a*) The classes and chemical properties of hydrated lime shall be determined by standard methods of chemical analysis. (*b*) The non-volatile portion of hydrated lime shall conform to the following requirements as to chemical composition:

CHEMICAL COMPOSITION

Properties considered	High-calcium	Calcium	Magnesian	High-magnesian
Calcium oxide, per cent . . .	90 (min)	85–90	. . . .	. . . .
Magnesium oxide, per cent	. . . .	. . . .	10–25	25 (min)
Silica plus alumina plus oxide of iron, max, per cent	5	5	5	5
Carbon dioxide, max, per cent .	5	5	5	5
Water.	Sufficient to hydrate the calcium-oxide content	Sufficient to hydrate the calcium-oxide content	Sufficient to hydrate the calcium-oxide content	Sufficient to hydrate the calcium-oxide content

II. Physical Properties and Tests

6. FINENESS. A 100-g. sample shall leave by weight a residue of not over 5% on a standard 100-mesh sieve and not over 0.5% on a standard 30-mesh sieve.

7. CONSTANCY OF VOLUME. Hydrated lime shall be tested to determine its constancy of volume in the following manner: Equal parts of hydrated lime under test and volume-constant Portland cement shall be thoroughly mixed together and gauged with water to a paste. Only sufficient water shall be used to make the mixture workable. From this paste a pat about 3 in in diameter and ½ in thick at the center, tapering to a thin edge, shall be made on a clean glass plate about 4 in square. This pat shall be allowed to harden 24 hours in moist air and shall be without popping, checking, cracking, warping

or disintegration after 5 hours' exposure to steam above boiling water in a loosely closed vessel.

III. Packing and Marking

8. PACKING. Hydrated lime shall be packed either in cloth or paper bags and the weight shall be plainly marked on each package.

9. MARKING. The name of the manufacturer shall be legibly marked or tagged on each package.

IV. Inspection and Rejection

10. INSPECTION. (*a*) All hydrated lime shall be subject to inspection.

(*b*) The hydrated lime may be inspected either at the place of manufacture or the point of delivery, as arranged at the time of purchase.

(*c*) The inspector representing the purchaser shall have free entry, at all times while work on the contract of the purchaser is being performed, to all parts of the manufacturer's works which concern the manufacture of the hydrated lime ordered. The manufacturer shall afford the inspector all reasonable facilities for inspection and sampling, which shall be so conducted as not to interfere unnecessarily with the operation of the works.

(*d*) The purchaser may make the tests to govern the acceptance or rejection of the hydrated lime in his own laboratory or elsewhere. Such tests, however, shall be made at the expense of the purchaser.

11. REJECTION. Unless otherwise specified, any rejection based on failure to pass tests prescribed in these specifications shall be reported within five working days from the taking of samples.

12. REHEARING. Samples which represent rejected hydrated lime shall be preserved in air-tight containers for five days from the date of the test-report. In case of dissatisfaction with the results of the tests, the manufacturer may make claim for a rehearing within that time.

Neat Lime. A number of lime manufacturers are at present making a product called NEAT LIME under various trade names. It is composed of various percentages of lime and cement together with hair or fiber, and is used for interior plastering as well as exterior stucco. It is sold in 50-lb paper sacks, and when mixed with sand and water is ready for use. This material, being more sound-absorbing than the gypsum plaster and not being injured by dampness or exposure to water as in the case of gypsum, has certain advantages. In some cases on exterior work an additional amount of cement is added to this neat lime to give it greater strength.

Useful Data on Quicklime. Quicklime is shipped either in barrels or in bulk. In dry climates it will keep for a long time in bulk, but in damp climates and along the coast it soon slakes unless enclosed in barrels By Act of Congress, August 23, 1916, it is required that lime in barrels shall be packed only in barrels containing 280 lb or 180 lb, net weight. When shipped in bulk it is generally sold by the bushel of 80 lb, 3½ bushels or 280 lb, net, of lime being considered as equivalent to a large barrel. Other weights are 180 lb, net, per small barrel, and 64 lb per cu ft. The average yield of LIME-PASTE from the best Eastern limes has been found to be 2.62 times the bulk of unslaked lime. A barrel of good quality well-burned lime should make 8 cu ft, or 20 pails, of lime-paste or putty. Careful experiments conducted by United States engineers have demonstrated that the best mortar is obtained by mixing one part of lime-paste to two parts of sand.

SAND AND GRAVEL

Sand is obtained from banks or pits, from river-beds and from the seashore. Pit-sand or bank-sand, free from clay or earthy materials, is generally considered the best for mortar, although excellent sand is often obtained from river-beds. Sea-sand contains alkaline salts which attract and retain moisture and which, unless thoroughly washed, cause efflorescence when used in brickwork. Both sea-sand and river-sand have more or less rounded grains, to which lime or cement will not adhere as well as to sharp, angular grains. Both are extensively used, however, for lack of better materials. The use of sand in mortar is to prevent excessive shrinkage and to save the cost of lime or cement. Sand, when used in the proportion of 1:2, strengthens lime mortar, but any addition of sand to cement weakens it.

Screening Sand. Sand for mortar must ordinarily be screened. Sand for brown mortar for plastering or common brickwork is ordinarily run through a No. 4 screen having 4 by 4 meshes to the inch. For sand finish and mortar for pressed brickwork, either a No. 10 or a No. 12 screen with 10 by 10 or 12 by 12 meshes to the inch is commonly used. For rubble stonework the sand is not ordinarily screened, unless it contains much gravel, in which case it should be screened through a 3/8-in mesh.

Weight of Sand. Dry sand weighs from 80 to 115 lb per cu ft. The average weight of damp (not wet) sand is about 96 lb per cu ft., or about 2 600 lb per cu yd. The voids for ordinary sand range from 0.3 to 0.5 of the volume, the average for screened sand suitable for mortar being 0.35 of the volume. The more uneven the grains in size the smaller the percentage of the voids. A one-horse load of sand contains about 22 cu ft. Two-horse loads vary from 1¼ to 2 yd. 1¼ yd is a fair load, 1½ yd a good load and 2 yd a large load.

PLASTER LATH, LATHING AND PLASTERING

Wooden Laths should be well seasoned, free from sap, bark and dead knots. Bark on laths is quite sure to stain the plaster. White pine is generally considered the best wood for laths, although spruce and hemlock laths are much used. Hard pine is not a good material, as it contains too much pitch. The regular size of laths is ¼ in by 1½ in by 4 ft. The width and thickness vary somewhat in different mills. Laths are sold by the thousand, in bundles containing 100 laths.

Metal Lathing. (See Chapter XXII.)

Insulation Boards made of cane and wood fiber, cork, etc., are now being used extensively as a base for plaster work. Care must be exercised in their erection, however, so that warping may be reduced to a minimum. It is advisable that the instructions given by the manufacturer be carefully followed.

Plastering on laths is generally done in three coats. The first coat is called the SCRATCH-COAT; the second, the BROWN COAT, and the third, the WHITE COAT, SKIM-COAT, or FINISH. On brickwork or stonework the scratch-coat is generally omitted. For first-class work each coat should be permitted to dry thoroughly before the next coat is applied, and under no circumstances should the finish-coat be applied before the brown coat is thoroughly dry. When plastering is applied to insulation boards two-coat work is often found to be adequate.

Drawn Work is a brown coat applied to a scratch-coat from the same staging, immediately after the scratch-coat is applied. It is a little cheaper than DRY SCRATCH, and much of it is done in the Western States.

The Scratch-Coat should always be made rich in lime, and should contain 1¼ bu of hair, or an equivalent quantity of fiber to each cask of lime, or 1 bu of hair to 2 of lime. A proportion of one part lime-paste to two parts of sand will require 1 cask (2½ bu) of lime to 5½ bbl of screened sand.

The Brown Coat should contain 1 cask (2½ bu) of lime to 7 bbl of screened sand, and 1 bu of hair to 5 of lime. Very little plaster is mixed by measure, however, the usual custom being to mix as much sand with the slaked lime as the mortar-mixer thinks it will stand and give satisfaction, the tendency being always to make the lime go as far as possible.

The Third or Finishing Coat is designated by various terms, such as SKIM-COAT, WHITE COAT, PUTTY-COAT, SAND-FINISH, etc. The skim-coat as used in the Eastern States is generally composed of lime-putty and washed beach-sand in equal proportions.

Sand Finish, which has a rough surface resembling coarse sandpaper, is mixed in the same way, only that coarser sand and more of it is used, and it is finished with a wooden or cork-faced float.

White Coating or Hard Finish generally means a composition of lime-putty and plaster of Paris, to which marble-dust is sometimes added. Plaster of Paris and marble-dust when used should not be mixed with the lime-putty until a few moments before using, and no more should be prepared at one time than can be used up at once, as it soon SETS, after which it should not be used. The skim-coat or hard finish should be finished with a steel trowel and wet brush. The more the work is troweled the harder it becomes. A superior hard finish is obtained by mixing 4 parts of Best's Keene's cement to 1 part lime-putty.

Mortar by Plastering. To make sure that the lime is well slaked, it is customary to require that the mortar for plastering shall be mixed at least seven days before it is used.

Hair such as is used by plasterers is obtained from the hides of cattle, and after being washed and dried is put up in paper bags, each bag being supposed to contain 1 bushel of hair when beaten up. Each package is supposed to weigh from 7 to 8 lb but the weight often falls short. ASBESTOS and MANILLA FIBER are both used in place of hair; they are cleaner than hair and are said to be less injured by the lime. It is much better to add the hair to the lime-paste AFTER IT IS COLD and before mixing in the sand, as hot lime, and the steam caused by the slaking, burn or rot the hair so as to greatly weaken it. The common practice is to put the hair in the mortar-box, run off the hot lime as soon as it is slaked, throw in the sand and mix the whole together. It is then thrown out of the box into a pile and a new batch mixed up.

Machine-Made Mortar. In many cities plants have been equipped for the mixing of mortar by machinery. Machine-mixed mortar is better than the ordinary hand-mixed mortar, for the reason that time can be given for the lime to slake, the lime and sand can be accurately measured, and the hair and lime are not mixed with the lime until just before delivery. The mixing may also be more thoroughly and evenly done by machinery than is possible by hand.

Improved Wall-Plasters. Owing to the difficulty of obtaining sufficient space in building operations in central sections of large cities to properly slake sufficient lime mortar to carry on the plastering with the necessary speed, other

kinds of plastering materials have come into existence in recent years. These are known as GYPSUM PLASTERS or HARD-WALL PLASTERS. The base of these products is calcium sulphate or gypsum which has been calcined to partially expel the water. The setting and hardening of these products is dependent upon their combining chemically with the gauging water and crystallizing in the same chemical form as the material possessed before calcination. All hard-wall plasters contain material added for the purpose of controlling the SET. The straight calcined gypsum sets in a very few minutes, which time would be entirely too short to permit the workmen to apply the plaster to the wall and straighten it up before it had set. These plasters are characterized, also, by their inability to carry as much sand as lime mortar. Many of them contain other substances, such as clay or hydrated lime, added to improve their PLASTICITY. Hard-wall plasters manufactured in the eastern part of of the United States from rock-gypsum invariably contain 15%, more or less, of clay or hydrate, added for this purpose. Plasters made in Kansas, Oklahoma, Texas and other Western and Southwestern States are made from earth-gypsum. In the case of these materials, clay and hydrated lime are not added, for the reason that the earth-gypsum contains considerable clay matter, which renders further additions unnecessary.

Use of Hard-Wall Plasters. Hard-wall plasters are found to be very convenient in cases where space and time are the most important elements in the building operation. They set more rapidly than lime plasters, thus permitting the white coating and finishing of the job to be completed earlier. While hard-wall plasters become extremely hard, this property is sometimes considered objectionable, as it may give rise to what is called the SOUNDING-BOARD effect.

Keene's Cement Plasters. As distinguished from the ordinary hard-wall plasters, there exists another class of gypsum-products which, however, are somewhat different in the method of preparation and behavior. In the manufacture of these materials, the gypsum is calcined, immersed in a bath of alum or similar chemical and recalcined. The name KEENE'S CEMENT is usllly applied to these materials, which are made by several manufacturers in this country. These are slow-setting and ultimately attain great strength and hardness. Keene's cement is generally used with considerable lime-putty or hydrated lime. The use of equal parts of hydrated lime and Keene's cement in making a plastering material is often recommended and found in specifications. (See Neat Lime.)

Advantages of Improved Wall-Plasters. Among the advantages gained by the use of these plasters are uniformity in strength and quality, extra hardness and toughness, freedom from pitting, saving in time required in making and drying, minimum danger from frost while being applied and before set, less weight and moisture in the building, and, in some cases, greater resistance to the action of fire.

Measuring Plasterers' Work. Lathing is always figured by the square yard and is generally included with the plastering, although in small country towns the carpenter often puts on the laths. Plastering on plane surfaces, such as walls and ceilings, is always measured by the square yard, whether it is one-coat, two-coat, or three-coat work, or lime or hard plaster. In regard to deductions for openings, custom varies somewhat in different parts of the country and also with different contractors. Some plasterers allow one-half the area of openings for ordinary doors and windows, while others make no allowance for openings of less than 7 sq yd.

Miscellaneous Details. Returns of chimney-breasts, pilasters and all strips less than 12 in in width should be measured as 12 in wide. Closets, soffits of stairs, etc., are generally figured at a higher rate than plain walls or ceilings, as it is not as easy to get at them. For circular or elliptical work, domes or groined ceilings, an additional price is made. If the plastering cannot be done from trestles an additional charge must be made for staging.

Cornices and Moldings. Stucco cornices and molded work are generally measured by the superficial foot, measuring on the profile of the molding. When less than 12 in in girth they are usually rated as 1 ft. For each internal angle 1 lin ft should be added, and for external angles, 2 lin ft. For cornices on circular or elliptical work an additional price should be charged. Enriched moldings are generally figured by the linear foot, the price depending upon the design and size of the mold.

Quantities of Materials for Lathing and Plastering

Miscellaneous Data. To cover 100 sq yd requires from 1 400 to 1 500 laths, or say 1 450 for an average job, and 10 lb of threepenny fine nails.

Three-coat plastering on wooden laths, plaster-of-Paris finish, will require from 10 to 12 bu of lime, 1½ cu yd of sand, 2 bu of hair and 100 lb of plaster of Paris per 100 sq yd.

If the finish-coat is omitted, deduct 2 bu of lime and all of the plaster of Paris.

If sand-finished, omit the plaster of Paris and add ½ cu yd of sand.

To cover 100 sq yd with two coats on brick or stone walls, the brown coat and finishing coats, will require from 8 to 10 bu of lime, 1½ cu yd of sand, and 100 lb of plaster of Paris, to 100 sq yd.

Using Best's Keene's cement for brown mortar and Keene's finish on expanded-metal lath will require, for brown mortar, 550 lb of cement, 5½ bu of lime, 2 cu yd of sand and 2 bu of hair; for the finish, 300 lb of cement and 1 bu of lime per 100 yd.

Hard plasters on expanded metal lath, plaster-of-Paris finish, require, for brown mortar, 2 000 lb of plaster and 2 cu yd of sand; for the finish, 1 bu of lime and 100 lb of plaster of Paris per 100 yd.

DATA ON LUMBER AND CARPENTERS' WORK

Relative Hardness of Woods. Taking shell-bark hickory as the highest standard of our forest-trees, and calling that 100, other trees will compare with it for hardness as follows:

Shell-bark hickory	100	Yellow oak	60
Pignut hickory	96	Hard maple	56
White oak	84	White elm	58
White ash	77	Red cedar	56
Dogwood	75	Wild cherry	55
Scrub-oak	73	Yellow pine	54
White hazel	72	Chestnut	52
Apple-tree	70	Yellow poplar	51
Red oak	69	Butternut	43
White beech	65	White birch	43
Black walnut	65	White pine	30
Black birch	62		

Weight of Rough Lumber per 1 000 Feet

BOARD-MEASURE, APPROXIMATE

Kind of wood	Green from saw, lb	Shipping-dry, lb	Well-seasoned, lb	Kiln-dried, lb
Ash	...	...	...	...
Chestnut	4 600	...	3 500	3 200
Hemlock	4 200	3 000	...	...
Maple, hard	5 400	4 150	3 900	3 400
Maple, soft	5 000	3 650	3 300	3 000
Oak, red	5 500	4 250	4 000	3 400
Oak, white	5 700	4 500	4 100	3 600

Pine, white	3 500	2 500	2 400	2 200
Poplar	4 000	3 000	2 900	2 400
Spruce	3 150	2 700	2 300	2 200
Sycamore	4 750	3 200	3 000	...
Walnut, black	4 900	4 000	3 800	...

Framing-Lumber may commonly be purchased in any of the following nominal sizes, except that common pine, spruce, and hemlock cannot usually be obtained in larger sizes than 12 by 12 in.

Nominal Sizes of Framing-Lumber

in	in	in	in
2 × 4	3 × 6	4 × 12	8 × 12
2 × 6	3 × 8	4 × 14	8 × 14
2 × 8	3 × 10	6 × 6	10 × 10
2 × 10	3 × 12	6 × 8	10 × 12
2 × 12	3 × 14	6 × 10	10 × 14
2 × 14	3 × 16	6 × 12	10 × 16
2 × 16	4 × 4	6 × 14	12 × 12
2½ × 12	4 × 6	6 × 16	12 × 14
2½ × 14	4 × 8	8 × 8	12 × 16
2½ × 16	4 × 10	8 × 10	14 × 14
...	...	...	14 × 16

In some of the New England mills, the following sizes, also, are sawed: 2 by 3, 2 by 5, 2 by 7, 2 by 9, 3 by 4 and 3 by 5 in. These sizes are not commonly carried in stock, and in most localities would have to be obtained by ripping larger sizes. Most of the long-leaf yellow pine and Douglas fir is SHIPPED SURFACED ONE SIDE AND EDGE, the actual dimensions being from ¼ in to ⅜ in, and sometimes ½ in, scant of the nominal dimensions. When framing-lumber is required to be full to dimensions it should be ordered IN THE ROUGH, and a special contract made on that understanding.

Lengths of Framing-Timbers. All timber is cut and sold in even lengths, as 10, 12, 14, 16, 18, 20 ft, etc. Odd and fractional lengths are counted as the next higher even length; consequently it is, in certain cases, possible and economical to plan buildings so that timbers of even lengths may be used without waste.

Measurement of Rough Lumber. All rough lumber is sold by the foot, BOARD-MEASURE, one foot being the equivalent of a board 1 ft wide, 1 ft long, and 1 in thick. To compute the board-measure in any board, plank, or timber, divide the nominal sectional area, in inches, by 12, and multiply by the length in feet. Thus the number of FEET in a 2 by 4-in scantling, 8 ft long = $(2 \times 4/12) \times 8 = 5\frac{1}{3}$ ft, board-measure. A 10-in board, 12 ft long, contains $(1 \times 10/12) \times 12 = 10$ ft, board-measure. Extensive tables are published showing the feet, in board-measure, for almost any commercial size of timber. The following table, however, although compact, will enable one to readily estimate the number of FEET in any of the standard sizes of boards, planks, or timbers. To use the table, find the product of the lateral dimensions of the cross-section; then in the column having a heading equal to this product, and in the horizontal line opposite the given length will be found the number of feet in board-measure. Thus, for a 3 by 4, 2 by 6, or 1 by 12-in timber look in the column headed 12; for a 2 by 12, 4 by 6, or 3 by 8-in piece, look in the column headed 24. For lengths not given in the table, take either twice the length and divide by 2, or one-half the length and multiply by 2. Where timbers of the same size abut end to end, it economizes labor in reducing to board-measure to take the full length; for this reason the lengths in the table are carried beyond those for single sticks.

Measurement of Finishing-Lumber, Flooring, Ceiling, Etc. Most, if not all, lumber for finishing is sawed for use in thicknesses of 1 in, $1\frac{1}{4}$ in, $1\frac{1}{2}$ in, and 2 in, and some woods, such as white pine and poplar, are sawed into thicknesses of $2\frac{1}{2}$ in and 3 in.

When surfaced both sides, the thickness is reduced to $\frac{13}{16}$, $1\frac{1}{16}$, $1\frac{5}{16}$, $1\frac{3}{4}$, $2\frac{1}{4}$, and $2\frac{11}{16}$ in.

All dressed stock is measured and sold STRIP-COUNT, that is, full size of rough material necessarily used in its manufacture. Thus $1\frac{1}{16}$-in boards are measured as though $1\frac{1}{4}$ in thick. The number of feet, board-measure, for $1\frac{1}{4}$-in stock ($1\frac{1}{16}$ finished) is $1\frac{1}{4}$ times that in a 1-in board, and in the same way for $1\frac{1}{2}$-in and $2\frac{1}{2}$-in stock. $1\frac{3}{4}$-in planks are always measured 2 in thick, and $2\frac{1}{4}$-in stock, $2\frac{1}{2}$ in thick. Boards less than 1 in thick are measured the same as 1-in boards, but for $\frac{3}{8}$-in and $\frac{5}{8}$-in stock a reduced price is generally made.

Matched Ordinary Flooring. The standard sizes for flooring (other than hardwood, parqueting or parquet-flooring) are 1 by 3, 1 by 4 and 1 by 6; or $1\frac{1}{4}$ by 3, $1\frac{1}{4}$ by 4 and $1\frac{1}{4}$ by 6. The thickness of 1-in flooring should be $\frac{13}{16}$ in, and of $1\frac{1}{4}$-in flooring, $1\frac{3}{32}$ in. 3-in flooring should show $2\frac{1}{4}$ in on the face, after it is laid; 4-in, $3\frac{1}{4}$ in; and 6-in, $5\frac{1}{4}$ in.

Matched Maple Flooring is usually made in 2-in, $2\frac{1}{4}$-in and $3\frac{1}{4}$-in face, and in thicknesses of $\frac{13}{16}$, $1\frac{1}{16}$ and $1\frac{5}{16}$ in.

Ceiling, matched and beaded boards, are regularly made in the same widths as flooring. The standard (nominal) thicknesses of yellow-pine ceiling are $\frac{3}{8}$, $\frac{1}{2}$, $\frac{5}{8}$ and $\frac{3}{4}$ in, the actual thickness of each being $\frac{1}{16}$ in less. The $\frac{3}{8}$-in ceiling is dressed one side only, the other thicknesses both sides.

Yellow Pine Drop-Siding. Dressed and matched yellow pine drop-siding is $\frac{3}{4}$ by $3\frac{1}{2}$ and $\frac{3}{4}$ by $5\frac{1}{2}$ in, showing $3\frac{1}{4}$ and $5\frac{1}{4}$-in face; and worked shiplap is $\frac{3}{4}$ by $3\frac{1}{2}$ and $\frac{3}{4}$ by $5\frac{1}{2}$ in, showing 3 and 5-in face.

Beveled Siding is resawed on a bevel from stock $\frac{13}{16}$ by $3\frac{1}{2}$ and $\frac{13}{16}$ by $5\frac{1}{2}$ in, after surfacing.

* The measurements in these columns come out in even feet.

New England Clapboards are 4 ft long, 6 in wide, ½ in thick at the butt, and about ⅛ in thick at the other edge. They are put up in bunches and sold by the thousand.

Rules for Estimating Quantities of Sheathing, Flooring, Etc. For common sheathing laid horizontally on a wall or roof without openings, add one-tenth to the actual superficial area to allow for waste. On the walls of dwellings, figure the walls as though without openings and allow nothing for waste. If sheathing is laid diagonally, add one-sixth to the actual superficial area.

For tight sheathing laid horizontally, add one-fifth for 6-in boards, one-seventh for 8-in boards, and one-ninth for 10-in boards. If laid diagonally add one-fourth for 6-in boards, one-sixth for 8-in boards, and one-eighth for 10-in boards.

For 3-in matched flooring add one-half to the actual superficial area to be covered.

For 4-in flooring add one-third and for 6-in flooring add one-fifth. Ceiling is measured the same as flooring.

For drop-siding, add one-fifth to the superficial area.

For lap-siding, laid 4 in to the weather, add one-half to the actual superficial area; if 4½ in to the weather, add one-third.

BUILDING PAPERS, BUILDING FELTS, QUILTS AND INSULATORS

Sheathing-Papers,* Felts, Quilts, Etc. It is well known that frame buildings when merely sheathed and clapboarded or shingled on the outside and simply lathed and plastered on the inside, are almost sure to be hot in summer and cold in winter; and as the wood almost always shrinks, cracks result through which the wind finds its way. For these reasons some extra provision should be made for keeping out the wind and the heat and cold; and it is generally admitted that there is no material that will do this so well and at so small an expense as good sheathing-papers or sheathing-felts. The papers made for this purpose are commonly known as SHEATHING-PAPERS or BUILDING PAPERS. There is a great variety of sheathing-papers manufactured, many of them of great excellence, and even the best are comparatively inexpensive; so that only the better qualities of any kind of felt or paper should be specified. Where the cost of the sheathing-paper on an ordinary house is only a few dollars, it is poor economy to use a cheap paper, as the labor of applying it is an important item and the poorer the paper the more difficult the work of putting it on. The qualities which good sheathing-paper should possess are: permanence, impenetrability to air and water and sufficient strength to permit of applying without tearing. Protection or proof against vermin and insects is another important requirement. It should not be brittle nor have a lasting strong odor and, for the convenience of the builder, should be clean for handling. There are so many papers possessing all or most of these qualities that it is deemed inexpedient to mention particular brands. The architect should decide for himself, from the samples with which he has probably been furnished, what papers are best adapted to the particular conditions; and he should then specify those brands, giving, also, the manufacturers'

* The terms BUILDING PAPER and SHEATHING-PAPER are by the public indiscriminately applied to all kinds of paper used in connection with building-construction. In the trade, however, the term BUILDING PAPER is confined to the rosin-sized and cheaper grades of paper, while the heavier and better grades are classed as SHEATHING-PAPERS.

names, instead of leaving the choice to the builder, who will be quite sure to be guided by price rather than by quality. Many object to tarred or saturated sheathing-papers and felts because of their tendency to become brittle and because they emit a strong odor and are somewhat disagreeable to handle. On the other hand, the advocates of tarred felts emphasize their cheapness, warmth and even their odor, which makes them vermin-proof. The odor gradually disappears after the clapboards, siding or shingles are put on and the inside walls finished. Sheathing-paper is usually applied just previous to putting on the clapboards, siding, or shingles. It is generally placed horizontally and should lap about 2 in over each sheet and over the paper previously placed around the window and door-frames. If sheathing-quilt or similar material is to be placed under the clapboards or siding, laths should be nailed vertically over it, opposite each stud, and the siding or clapboards nailed to the laths; otherwise it will be difficult to put them on evenly, owing to the thickness and elastic quality of the QUILT. Shingles, however, may be applied directly over it. Sheathing-quilt possesses marked fire-resisting properties. The sheathing-paper and the labor of putting it on should be included in the carpenter's specifications.

Insulating Boards. Of recent years, insulating boards have been used extensively to insulate walls, floors and ceilings. This material has been found especially useful for attics and roofs in preventing heat losses. These boards are made of cork and wood fibers; they possess considerable strength, and as well as serving as insulators, they are used extensively as bases for plastering.

Loose Fill. Another material now used is a loose fill consisting of granules of fibrous or flaky materials, possessing no strength, but useful as an insulating fill between studs, joists and roof-rafters.

Rosin-Sized Building-Papers. These are the common grades of building paper; they are not water-proof, and should not be used on roofs or on walls in damp climates. In dry places they protect from dust, draughts, and to some extent from heat and cold. They are generally either a dull red or gray in color, have a hard, smooth surface, and are clean to handle. They are always put up in rolls 36 in wide and usually contain 500 sq ft. The weight varies from 18 to 40 lb to the roll of 500 sq ft.

Insulating and Deadening-Quilts. Among the insulating and deadening-quilts much in use are those mentioned below. There are also other good materials in this line which are manufactured and used for insulating and deadening purposes

Sheathing-Quilt.* This consists of a felted matting of eel-grass held in place between two layers of strong paper by quilting. "The long, flat fibers of eel-grass cross each other at every angle and form within each layer of quilt innumerable minute dead-air spaces, that make a soft, elastic cushion. This gives the most perfect conditions for non-conduction" Eel-grass is chosen for the filling because of its long, flat fibers, which especially adapt it for felting; because of its great durability, and its resistance to fire; and because, owing to the large percentage of iodine which it contains, it is repellent to rats and vermin. This quilt is made in single, double and triple-ply thickness, and is put up in bales of 125 and 250 sq ft. It is also now made with a covering of asbestos, which tenders it thoroughly fire-proof, and also with a water-proof covering to resist moisture. The material is also efficient for heat-insulation.

* Made by Samuel Cabot (Inc.), Boston, Mass.

When used for this purpose there is no objection to nails passing through it. Quilts are made with bevel edges to permit rapid lap installation.

Keystone Hair Insulator. Another material used for similar purposes is the Keystone Hair Insulator. This consists of thoroughly cleansed cattles' hair, between two layers of strong, non-porous building paper, securely stitched together. The hair is chemically treated, so that it is coated with lime, which makes the finished material vermin-proof and odorless.

Mineral-Wool Deadeners, which are fire-proof sound-deadening quilts of rock-fiber wool stitched between two sheets of building paper or of asbestos paper according to the grade desired, are made by the Union Fibre Company of Winona, Minn., and other firms. This company makes, also, what is called Lith and Feltlino, which are sound-deadening materials in board form. They manufacture, also, Linofelt, a building-quilt of flax-fibers (unbleached linen threads), stitched between water-proof paper or asbestos paper according to need. It is ¼ in thick. Linofelt for sheathing in place of ordinary building paper adds from 1 to 1½% to the cost of a house.

Felt-Papers. There are a great many felt-papers for lining floors and a few are made fire-proof by means of chemicals. As a rule these felts are cheaper than Cabot's QUILT, although the saving in an ordinary residence would be but little, and even among the felts themselves there is quite a difference in cost. In choosing a felt-paper for lining, the architect should select one that is soft and elastic enough to form a cushion, and the thicker the felt, provided it has the above qualities, the greater will be its non-conduction. Some felts are made water-proof by an asphalt center, which is an advantage in case of fire or leaks, but some authorities think that it is doubtful if such felts obstruct the passage of sound as well as felts without the asphalt center. The experience of some acoustical experts seems to show that one of the best methods of deadening is by a combination of heavy hair-felt or felt-paper with sheets of galvanized iron. Two layers of felt, each from ½ to 1 in thick, are placed on either side of a single layer of galvanized iron, the latter resting freely between the felt layers. This form of construction is to be preferred where the deadening-material is not attached to the enclosing woodwork. An additional layer of iron and of felt increases the effectiveness of the combination.

Saturated Felts. Common roofing-felts are made by saturating common dry felt with coal-tar pitch. Roofing-felts are commonly made in weights of 12, 15, and 20 lb to the 100 sq ft. Nothing lighter than 12 lb should be used for roofing. They are usually sold by weight. Asphalt-felts are commonly made in the same weights.

Dry Saturated Tarred Felts are specially run through a tier of calenders to give a hard, uniform surface and contain a minimum amount of coal-tar. They are especially adapted for slaters' use, as they will carry a chalk line and are easy to handle. The rolls are 36 in wide, contain 500 sq ft and weigh about 30 lb.

Asbestos Building Felts are usually made about 6, 10, 14 and 16 lb to the 100 sq ft, although different manufacturers make different weights. They come in rolls 36 in wide and are sold by weight.

Sound-Deadening Felts. These deadening-felts are made by various manufacturers. In one of these felts * the material itself is rather hard and thin, but it is pressed in such a way as to form small indentations or air-cells. This makes it elastic and breaks up the sound-waves.

* Neponset Florian Sound-Deadening Felt.

Asbestos Sheathing. Sheathing-papers or building felts, made of asbestos, are used to a considerable extent for floor-linings and for covering the outside walls of wooden buildings, principally on account of their fire-proof and vermin-proof qualities. These papers are well known in the trade and can be procured without difficulty. They are supplied by the manufacturers in 50 or 100-lb rolls, 36 in wide, on a basis of the following scale of weights:

4 lb to the 100 sq ft	18 lb to the 100 sq ft
6 lb to the 100 sq ft	20 lb to the 100 sq ft
8 lb to the 100 sq ft	24 lb to the 100 sq ft
10 lb to the 100 sq ft	32 lb to the 100 sq ft
12 lb to the 100 sq ft	1/16 in thick
14 lb to the 100 sq ft	3/32 in thick
16 lb to the 100 sq ft	1/8 in thick

The sheathing in the 1/16, 3/32 and 1/8-in thicknesses is used only for special purposes where an unusually thick lining is desired for possible fire-protection around exposed flues, for chimney-breasts, etc. When the weight of paper exceeds 32 lb to the square foot it is known as ROLL-BOARD and is no longer classed by weight per 100 sq ft, but by thickness. For floor-linings, 16-lb paper is generally employed, this weight being sufficiently thick and strong to resist ordinary damage in application and in handling. Asbestos felts and building papers appear to have approximately the same effect in retarding the passage of sound-waves as other felt-papers of a relatively similar thickness and quality, while their fire-proof and vermin-proof qualities are a distinct advantage. The cost of asbestos paper and building-felt, while somewhat greater than that of the ordinary papers used for similar purposes, is not excessive. The market price varies and depends upon the fluctuations of the market.

Water-Proof Papers. Neponset Black Sheathing is water-proof and air-proof, odorless and clean to handle, and is an excellent paper under siding, shingles, slate, or tin. The rolls are 36 in wide, containing 250 and 500 sq ft.

Neponset Red Rope Sheathing and Roofing. This is made of rope-stock, has great strength and flexibility, and is absolutely water-proof and air-tight. It is one of the best sheathing-papers and makes a good cheap roofing for sheds, poultry-houses, etc. The rolls are 36 in wide, containing 100, 250 and 500 sq ft.

Parchment Water-Proof Sheathing. There are various parchment-sheathings on the market which are semitransparent, have smooth surfaces, and are odorless, water-proof, air-proof and vermin-proof. They are adapted for general sheathing purposes In general 1-ply weighs 25 lb to 900 sq ft; 2-ply, 25 lb to 500 sq ft; 3-ply, 25 lb to 275 sq ft. They are 36 in wide.

PAINT AND VARNISH *

Pigments and Vehicles. The solid ingredient of a paint is called the PIGMENT, and is a fine powder, nearly all of which will pass through a brass-wire sieve of 100 meshes to the linear inch; in fact, most pigments are much finer than that, and those formed as precipitates by chemical processes are so fine that there is no way to measure them. The liquid part is called the VEHICLE. This is usually linseed-oil, sometimes with the addition of a little

* The editor is indebted to Professor Alvah H. Sabin and the National Lead Co. of New York for valuable assistance in the revision of the data relating to this subject.

turpentine or other volatile solvent. In the enamel paints it is varnish and in kalsomine and other cold-water paints it is a solution of glue, casein, albumen, or some similar cementing material. The cementing material is sometimes called the BINDER.

Colloidal Paints.* "**Collopakes,**" a new kind of paint, is now made with pure pigments and without fillers. The pigments are not ground but are reduced to a great fineness, and colloidally dissolved in the vehicle. Because of an electrical charge incurred during the process of manufacture they settle very slowly over long periods of time. Advantages claimed by the manufacturer are that this paint does not become hard in the bottom of the container, penetrates the surface of the material to which it is applied, thus insuring against cracking and peeling. This paint is used for exterior and interior surfaces and may be used also as a waterproofing for stucco and brickwork.

Ingredients of Oil-Paint. White lead and white zinc are the common white pigments. Titanium oxide is now a common ingredient of white paint, most frequently as the product called "Titanox," which also contains barium sulphate; this is used in mixtures with white lead and white zinc, is chemically permanent and is white and opaque. There are white pigments of variable composition called leaded zinc and zinc lead, furnace-products, composed of zinc oxide and lead sulphate. There is also a basic lead sulphate, commercially called sublimed white lead, which is a similar furnace-product consisting chiefly of sulphate of lead. These composite white pigments are largely used in mixed paints. LITHOPONE is a mixture of sulphide of zinc and sulphate of barium. It is very white, fine and opaque and largely used as the basis of flat wall-finishes for interior work, but is not durable for exterior work. It is discolored (gray) by strong light, but this is not a very serious practical objection. White lead is used everywhere, but tends to yellow somewhat in the dark. White zinc is chiefly used on interior work, being the whitest paint known. Both are often mixed and both are used in mixed paints. Yellow paint is commonly chromate of lead, or chrome yellow; green is chrome green, which is a mixture of chrome yellow and Prussian blue; blue is ultramarine, or sometimes Prussian blue. The brilliant reds are coal-tar colors as a rule; the dull reds and browns are oxides of iron. Ochres are dull yellow. Carbon forms the base of all black paints, either as lampblack, dropblack (boneblack), or graphite. Linseed-oil is either raw or boiled. Raw oil is the oil in its natural state as it is extracted from the seed; it should be settled and filtered perfectly clear; it is yellow or greenish yellow in color. Boiled oil is raw oil which has been heated to 400° or 500° F. with compounds (usually oxides) of lead and manganese; it is darker in color than raw oil, and dries quicker. Raw oil exposed in a thin film to the air is converted in about five days into a tough leathery substance; boiled oil undergoes this change in from 10 to 24 hours.

Driers. These are compounds of lead and manganese, dissolved in oil, and this solution thinned with turpentine or benzine. They act as carriers of oxygen between the air and the oil, and their addition to a paint makes it dry more rapidly. Some driers are also called JAPANS. Not more than 10% by volume of any of these liquid driers should be added to oil. Excess of drier causes the paint to lack durability. Cheap driers often contain rosin. It is well to specify that driers and japans should be free from ROSIN (not resin, as varnish-resins are present in some of the best driers).

* **Manufactured by Samuel Cabot, Inc., of Boston, Mass.**

Priming Coat. This is the first coat applied to the clean surface. A priming coat for wood is chiefly oil, and is usually equivalent to a gallon of ordinary paint thinned with a gallon of raw linseed-oil. Paint, however, is not thinned to make a priming coat for structural metal. In all wood-work, nail-holes and other defects are filled with putty after the priming coat has been applied; but if the wood is resinous, knots and resinous places must be covered with shellac varnish before the priming coat is put on. Pitchy woods, such as southern yellow pine and cypress, do not readily absorb oil, and turpentine should be substituted for part of the oil. Red lead is successfully used as a primer (2 parts to 1 of white lead) on such woods; this is the standard practice in England, and is better than the use of all white lead.

Outside Painting. The priming coat having largely been absorbed by the wood, a second and third coat of paint are to be applied. The most common paint used on houses is white lead. This is commonly sold as paste white lead, containing 8% of oil; 100 lb of this is equal to 2.8 gal in volume, and is commonly mixed with 3½ gal of raw linseed-oil, 1 qt of turpentine and 1 pt of drier to make 6⅔ gal of paint for the second coat; or with 4 gal of oil, 1 pt of turpentine and 1 pt of drier for the finishing coat. White lead is also put up as a soft paste containing 13% oil; 100 lb bulks 3 25 gal and calls for ¾ gal less oil than the heavy paste formulas. About half of the white-lead paste now made is soft paste because of the ease with which it can be converted into paint. If white zinc is used, 9½ lb of dry zinc oxide and 5.7 lb of oil make 1 gal of paint; to this, turpentine and drier should also be added. White lead, after about a year, begins to CHALK, that is, its surface becomes dry and chalky; this does not indicate failure, however, and it makes a good surface for repainting. Finely reticulated checking, not extending through the film, occurs later, and when sufficiently marked indicates need of repainting. In any paint, when cracks begin to extend through to the wood, repainting is called for; these cracks occur sooner on pitchy woods. White zinc, if used alone on outside (not inside) work, is very hard and tends to peel off. MIXED PAINTS (prepared proprietary paints) generally contain zinc mixed with either white lead or some of the pigments based on basic lead sulphate, and some auxiliary pigments, such as barytes, China clay, etc , ground in oil and turpentine and containing the necessary drier. The best of these are excellent, but some are very poor; the safest way to use them is to specify them by name, and use them according to the maker's directions. RIPOLIN and VITRALITE are types of a paint made with a vehicle consisting of pure linseed-oil heated a long time until it is a viscid liquid when cold; it is then thinned considerably with turpentine, and ground with a suitable pigment, such as white zinc, white lead or mixtures with titanox. Some drier is added. This kind of paint is not very opaque, gives a fairly bright enamel finish and is durable indoors. COLORED PAINTS are commonly made by adding colored pigments to lead or zinc; but some dark paints contain only iron oxides, ochers, etc., as pigments; these weigh from 12 to 14 lb per gal. Painting should always be done in dry weather and no painting should be done until the inside plastering is dry. Paint should not be applied to lumber that is not dry. A week or more should be allowed between successive coats. In painting the outside of a house, the trim should be painted first; then the body-color can be laid neatly against it. The final brushing should be in the direction of the grain of the wood. It is good practice to have the successive coats (except for white paint) vary a little in color, to facilitate inspection. White, light blue and light green are less durable colors than yellow, gray, or dark colors in general, owing to the fact that the chemical rays of light penetrate the former more easily. A

gallon of paint will cover from 400 to 600 sq ft of surface, depending upon the character of the surface. ROOF-PAINTS should contain a larger proportion of oil, and a smaller amount of drier or none at all. Three coats are desirable. Tin roofs and galvanized-iron work should be thoroughly scrubbed and then dried before painting. The shingles on the walls and roofs of a house are sometimes stained with creosote stain, which consists of a pigment suspended in creosote or some similar liquid. The creosote has some preservative effect.

Inside Painting. Door-frames and window-frames should receive a priming coat of paint in the shop; if they are to be finished in varnish this paint will be applied to the back only. As has already been said, before any painting is done any resinous knots should be varnished with shellac. All interior surfaces which are to be painted should be puttied after the priming coat and the putty should be applied with a wooden spatula, not a steel one, to avoid marring the surface. The paint for the second coat should contain as much turpentine as oil, that is, its vehicle should be half oil and half turpentine. The effect of this is to make the paint dry with a dull instead of a glossy surface, FLAT SURFACE being the painter's term. To this the next coat will adhere well. If the next is the final coat, it may be an ordinary oil-paint. When thoroughly dry the gloss may be removed by lightly rubbing it with pumice and water. ENAMEL PAINT consists of pigment with varnish as a vehicle. It is harder and makes a finer finish than oil-paint. It is also more expensive. It is usual to apply it over oil-paint, in which case the last coat of oil-paint should be lightly sandpapered when quite hard and dry. A coat of enamel paint is then put on, and when it is dry it should be sandpapered or rubbed with curled hair. The final coat of enamel is then laid on and it may be rubbed in a like manner if a flat surface is desired, or it may be left with the gloss. It is also common practice for painters to make a final enamel finish by adding varnish to white lead or white zinc, very little oil being used in this case. The best varnish for this purpose is a spar-varnish from a thoroughly reliable maker. The quicker-drying varnishes will crack and ALLIGATOR.

Varnish. There are two principal kinds of varnish, (1) spirit varnishes, of which shellac varnish is the most important, and which consists essentially of a resin dissolved in a volatile solvent, and (2) oleoresinous varnishes, in which the resinous ingredient is combined with linseed-oil, and this compound is dissolved in turpentine or benzine. The oleoresinous varnishes are commercially the more important, and are largely used in interior finishing. A gallon of varnish covers 500 sq ft, one coat. Surfaces to be varnished are treated in the following manner. If the wood is open-grained, as oak, chestnut, or ash, it first receives a coat of paste-filler. Liquid fillers are not desirable, as they form a poor base for subsequent work. A paste-filler is really a sort of paint, the pigment being silex, or ground quartz, and the vehicle is a quick-drying varnish made thin with turpentine or benzine. This is rubbed strongly in on the grain of the wood with a short stiff brush, and as soon as it has set, usually within half an hour, it is rubbed off with a harsh cloth or a handful of excelsior, the rubbing being hard across the grain of the wood. If it is desired to stain the wood, the oil-stain may be mixed with the filler; but if a close-grained wood is used, which needs no filler, the oil-stain may be thinned to the desired color with turpentine or benzine and applied as a wash. In cleaning the filler out of moldings, corners, etc., a suitably shaped stick, but not a steel implement, may be used. If any puttying is necessary it is done next. After two days the first coat of varnish is applied; after five days it should be rubbed with curled hair or fine sandpaper to remove the gloss, so that the next coat will adhere well; then one, two or three more coats of varnish are added, five

days or more apart, each coat being rubbed. The last coat may be rubbed or left with the natural gloss. Outside doors, window-sills, jambs, inside blinds, and all surfaces exposed to the direct rays of the sun, should be varnished with spar-varnish and left glossy. If shellac varnish is used as the interior finish it is applied in the same way, but at least six coats should be applied. Floors which are to be varnished should be treated as has been described; but if they are to be waxed they should receive one or two coats of shellac varnish, then five or six coats of wax, at intervals of a week, each coat being well polished with a weighted floor-brush made for the purpose. Floor-wax is not beeswax, but is a compound wax made for the purpose. Shellac is a good floor-varnish; it discolors the wood less than any other varnish, and dries rapidly.

Painting Plastered Walls. Plastered walls which must be painted are usually washed with a solution of soap and then with a solution of alum. When this is dry it is sponged off, then allowed to dry, then oiled, then painted. If the paint is applied to the fresh plaster the lime in the plaster will attack the paint.

Repainting. The exterior woodwork of a house needs repainting once in five to ten years, according to climate and other conditions, although if not done with proper material or sufficient care it will not last as long as this; the interior should, with good care, stand from fifteen to twenty years, and then may not require complete renewal. Exterior paint sometimes loses its luster, while the body of the paint is still good, and in cases of this kind it is sufficient to wash the surface and then give it a coat of oil. This replaces the oil which has superficially perished, imparts a gloss and brings out the color. If the paint is worn off so as to show the wood in places, or is peeling, it must be very carefully examined. In extreme cases it is necessary to BURN OFF the old paint; this is done with a painter's torch, a lamp which burns alcohol, naphtha, or kerosene, and which furnishes a flaring blast of flame, which is directed against the painted surface just long enough to soften the paint, which is at once removed with a scraper while still hot. The paint is not actually burned, but only softened by the flame; it may, however, be removed as well as softened by this method. Houses covered with pitchy wood, like southern pine, sometimes require this treatment, and the next painting is found to be more lasting. In many cases it is sufficient to thoroughly scrub the surface with a stiff steel-wire brush. Interior surfaces may be cleaned (if the removal of the old paint and varnish is necessary) with varnish-remover; this is a mixture of solvent liquids, which penetrate the old paint or varnish and soften it, when it may be removed with scrapers or brushes. There is less danger of fire with this method than with the burning-off method, but it is slower and costs more. It must not be forgotten that varnish-remover is volatile and highly inflammable and must not be used in a room where there is a fire. It is especially suitable for cleaning out moldings and all irregular surfaces from which the varnish may then be removed with stiff brushes, or with hardwood scrapers. It is especially desirable to have floors occasionally cleaned in this way; but if a house has been varnished originally with a first-class varnish it may be necessary only to wash it thoroughly and then apply another coat of varnish. Smoke and dirt may often be thoroughly removed from ceilings with the crumbs of fresh bread, where washing would not be desirable. A 10% solution of carbonate of soda (sal soda) in hot water may be used to remove old floor-wax.

The Painting of Structural Steel. Steel being usually more perishable than wood, as well as more expensive, and used for service where its strength is essential to the stability of the structure, its protection from corrosion by

painting is of much importance. It must first of all be recognized that the precaution always taken in painting wood, to secure a clean surface for the paint, must not be omitted with steel. Mud and dirt must first be removed from the steel; then it must be examined for rust, and any rust-spots must be thoroughly cleaned. Loose scale may be removed with wire brushes, but thick and closely adherent rust must be removed with steel scrapers, or with hammer and chisel if necessary. No doubt the best way to clean steel is to use the sand-blast, but it is not available for much architectural work. In any case much care must be taken to obtain a clean surface. On wood the priming coat sinks into the wood and forms a perfect bond between it and the succeeding coats; but on metal no such thing is possible and it is a case of simple adhesion, which demands a clean surface for efficient results. The paint for structural metal should be tough and elastic, and to as great a degree as possible it should be water-proof. Less than two coats should never be applied, and three are better. Paint is always thin on edges and angles, and also on bolt and rivet-heads; it is therefore good practice, after the first full coat, to apply a partial or striping coat, covering the angles and edges and the surface for at least 1 in back from the edges, and covering all bolt-heads and rivet-heads. After this striping coat has become dry, the second full coat is applied, and it may then be assumed that the whole surface has received two full coats. At least a week should elapse between coats. In designing the steelwork, all cavities which may be filled with rain during erection should be properly drained; and during erection all small cavities should be filled with cement, and all contact-surfaces thickly painted.

Kinds of Paint for Structural Steel. RED LEAD is more generally used than anything else as a paint for structural steel. It is a "true red lead" (Pb_3O_4), usually made from litharge (PbO), and frequently containing from 10 to 20% of the latter. If it contains much litharge, it rapidly thickens when mixed with oil and finally hardens; this makes it a paint difficult to apply. If, however, the material from which it is made is reduced to a sufficiently fine powder before it is oxidized, an almost completely oxidized red lead is produced, which is as easily worked as white lead, and better in every respect. The requirements of the government of the United States have for years called for red lead of not less than 94% of "true red lead" (Pb_3O_4), and the Navy Department, as well as several large railway companies, is now using large amounts of red lead which has not less than 98% of "true red lead." It may now be obtained in paste-form, similar to white lead and containing about 6½% of raw linseed-oil. Thirty-three pounds of red lead (dry pigment) to 1 gal of oil is the maximum; this is especially suitable for hydraulic work, and is the standard bridge paint on some of the largest railroads in this country, while in England 35 lb is standard on some large railway work; 28 lb to 1 gal of oil (containing 20 lb of pigment in a gallon of paint) is more common, while 25 lb to a gallon of oil is a common requirement for railroad-specifications. Finely ground GRAPHITE in linseed-oil is a favorite paint for metal; it flows well, is easily applied, less expensive than red lead, and if well made gives excellent results. Graphite is sometimes mixed with lampblack, probably with advantage. Boneblack is also an important ingredient of CARBON PAINTS. Formerly oxide of iron in linseed-oil was used more than all other paints for this purpose; but while many engineers still like it, its use has very greatly diminished. ASPHALTUM has been used and is still used, as a varnish either alone or in combination, and some of these asphaltic preparations are fairly satisfactory. The fact is, that a really competent paint-manufacturer can make a reasonably good paint out of any of these, and if the paint is carefully applied

the results will be satisfactory. There are great differences in painters. In regard to the surface of structural steel covered by a gallon of paint, there is a great difference of opinion among experts. Some say from 300 to 400 sq ft, others 1 000 or 1 200 sq ft. The truth is that any paint may be brushed out into an exceedingly thin film by a skilled workman, while ordinary usage results in a film at least twice as thick. The general opinion is that it is not wise to estimate more than 400 sq ft to the gallon for one coat. Varnish-paints cover less than oil-paints, but if well made they are very durable.

Painting on Cement and Concrete. Cement and concrete-work are difficult to paint, because they are strongly alkaline and even caustic when new. Work in these materials should be allowed to stand a year or two if possible before it is painted; then it may be painted with any ordinary paint. A practice which has been highly recommended is to wash the surface, repeatedly if possible, with a strong solution of zinc sulphate, the sulphuric acid uniting with the free lime and the zinc being left in the pores as an oxide or hydrate. Some preparations for this purpose are on the market; and while some are probably good, others are to be distrusted. The best way is to allow the surface to age, if this is at all possible.

WINDOW-GLASS AND GLAZING *†

Glazing. The glazing of windows originally belonged to the painter's trade, and when glass is broken, it is still customary to go to a painter to have it replaced; but custom has so changed in some parts of the country, that when new windows are to be glazed, the work is sometimes done at the mill or factory where the sashes are made, sometimes by the local glass-jobber in the town where the building is being erected, and again, in other localities, the glazing of new buildings is still done by the painter. COMMON WINDOW-GLASS is usually set with putty and secured with triangular pieces of zinc called GLAZIERS' POINTS or SPRIGS, driven into the wood over the glass and covered with putty. In the best work, a thin layer of putty is first put in the rebate of the sash and the glass is then placed on it and pushed down to a solid bearing. The glass is then sprigged and face-puttied after which the sash is turned over and the surplus putty removed with the putty-knife. This is called BEDDING IN PUTTY. Another method is as follows: The glass is placed in the sash, sprigged and face-puttied. The sash is then turned around and the glazier fills in any spaces that may occur between the glass and wood by forcing putty into such voids. This is called BACK-PUTTYING.

Leaded Glass. It was formerly a common practice for architects to name in the specifications a certain sum of money to be allowed by the carpenter for the leaded glass and to be expended under the direction of the architect. Where clear glass was used, the pattern was sometimes shown on the drawings and the glass was specified in the same manner as any other work. When colored glass was to be used, it was customary to make a definite allowance and then to entrust the work to a good art-glass manufacturer. But leaded glass should be designed, furnished and put in place by those who are entirely familiar with its manufacture and its limitations; the purchase of the same should be left entirely in the hands of the owner; and no specification as to its

* Condensed from an article by the late Professor Thomas Nolan.
Much valuable information on this subject has been obtained from the Hires-Turner Glass Co., Philadelphia, Pa.

† See also Glass and Wire-Glass, and Prism and Structural Glass, Article 5, Chapter XXII.

price or make should be used by the architect. The colored glass windows should show as much individual artistic taste as any other picture or decoration used in the building. The cheap and inartistic leaded glass is fast becoming a thing of the past and owners are confining themselves to purely works of art placed in some appropriate location in the building.

Sheet Glass. General Description. Common window-glass is technically known as SHEET GLASS. It is mostly made either by the Libby-Owens or the Fourcault process. The former draws the glass flat and upward from the end of the tank to a height of about 36 in, and then horizontally over a roller into a lehr through which the glass passes for annealing. It is cut off into sheets as it reaches the end of the lehr, a distance of about 200 ft. The Fourcault process also draws the glass in a flat sheet from a tank but it is drawn vertically to a height of about 16 ft, being quickly annealed during the process. The sheets are cut into standard lengths at the top of the draw. Practically no glass is now made by the old-style cylinder process.

Grades and Qualities of Sheet Glass. Sheet glass is graded as DOUBLE-THICK, or SINGLE-THICK, and each thickness is further divided into three qualities, FIRST, SECOND or THIRD, according to its relative freedom from defects. The price varies according to the strength and quality. It should be remembered that sheet glass is always more or less wavy, irrespective of the process by which it is made. Many suppose that by designating sheet glass, CRYSTAL SHEET GLASS, SELECTED-SHEET GLASS, or SHEET GLASS FREE FROM WAVES AND IMPERFECTIONS, a sheet glass free from waves and blemishes can be obtained. The terms and names do not change the nature of this glass, which still remains sheet glass, characterized by the defects inherent in the method by which it is manufactured. To obtain a thin glass, free from waviness, plate glass, 1/8 in thick, formerly known as CRYSTAL PLATE, or plate glass 3/16 in thick, must be specified. Since the improvement in the manufacture of window-glass in this country, scarcely any sheet glass is now imported for glazing purposes. A small amount of Belgian sheet glass is brought to this country and used along the Atlantic seaboard for picture-framing. The low prices of the American sheet glass, and its excellent quality, have practically forced imported sheet glass out of the market. All common sheet glass, without regard to quality, is graded according to thickness, as SINGLE-STRENGTH or DOUBLE-STRENGTH. The thickness of the double-strength glass is approximately 1/8 in while that of the single-strength averages about 1/10 in. It is customary to use the double-strength for sheet glass over 24 in in width. The best quality of sheet glass is specified as AA, the second as A and the third as B. Very little AA or first quality glass is obtainable. The standard for A quality is very high. All AA and A quality glass carries the manufacturer's label on each individual light and should be so specified.

Sizes of Sheet Glass. The regular stock sizes vary by inches from 6 to 16 in in width. Above that they vary by even inches up to 60 in in width and 70 in in length for double strength and up to 30 by 54 in for single strength. However, many sizes in these categories are non-standard sizes and have a higher base list price than standard sizes.

Crystal-Sheet Glass, 26-Ounce. This glass is made by the same process as common window-glass, and most double-strength glass now is 26-ounce. Owing to the method of its manufacture, it is necessarily characterized by a wavy appearance. If good glass is required for first-class residences, hotels, office-buildings, etc., polished plate glass should be used in either 1/8, 3/16 or 1/4 in thickness.

Defects of Sheet Glass. All sheet glass, when looked upon from the outside, has a wavy, watery appearance, like the surface of a lake slightly agitated by the wind; and when the sunshine falls upon it the irregularity of the surface is greatly emphasized. This characteristic of sheet glass is due to its method of manufacture and cannot be wholly avoided. Besides this universal defect, the cheaper grades are often STRINGY, BLISTERY, SULPHURED, SMOKED, or STAINED; so that, in looking through the glass, objects seen at a distance are deformed and distorted.

Plate Glass. General Description. Plate glass is commonly known as POLISHED PLATE GLASS because its surface is finely polished and thus made clear and transparent. It is more largely used every year for windows of fine residences, hotels and office-buildings, where transparency is desired from the inside and an elegant appearance required on the outside. The process of manufacture of plate glass is entirely different from that of sheet glass. In making plate glass the metal, which is prepared with great care, is melted in large pots and then either cast on a perfectly flat cast-iron table and flattened out by a heavy roller, or the Bichereoux process is used wherein the metal is poured onto an angular plane and flows of its own accord between two rollers, which determine its thickness, onto a large steel table which is moving slightly slower than the molten glass is flowing. The rough sheet of glass has thus been formed of the desired thickness and is, as in the former case, taken through a series of ovens and then a long lehr for annealing. The sheet then forms what is known as ROUGH PLATE, which is used for vault-lights, sky-lights, floor-lights and the like. For polished plate the rough plate is carefully examined for flaws, which are cut out, leaving the largest-sized sheet practicable. The old method of grinding and polishing by circular or revolving tables is fast becoming obsolete and is being supplanted by the straight-line continuous grinding and polishing method. In this method, the glass is fastened to large rectangular tables, by means of plaster of Paris, and then passes in a straight line under a number of grinding wheels, shod with cast iron. Sand and water are fed onto the surface. These grinding wheels. operated by electric motors, revolve, going over all parts of the plate, and grind it down to a true plane. Sand in successive degrees of fineness is fed on until the plate is made absolutely smooth and all grit removed. After this, the tables go on under a series of polishing machines shod with very fine felt, also operated by electric motors. Liquid rouge is added for the polishing. When one side is completed, the other side is similarly treated, the plate losing about 30% in weight by the operation.

Qualities of Polished Plate Glass. For glazing purposes there is but one quality of plate glass on the market. The best of this is selected for manufacturing mirrors. At one time, plate glass was extensively imported, but the gradually improving methods of the American manufacturers, as well as the great cheapening of the process, have practically eliminated imported plate glass from the market. The American plate glass is equal in every respect to that which was imported. The usual thickness of polished plate glass is from $\frac{1}{4}$ to $\frac{5}{16}$ in, but it can be made thinner than this; and when required for residence-windows or car-windows, may be obtained in $\frac{3}{16}$ or $\frac{1}{8}$-in thicknesses. The production of $\frac{1}{8}$-in plate glass has increased enormously in the past few years for two reasons: First, the demand for a thin ground and polished glass for use in residences and other buildings where a thick glass is not required; second, the demand for laminated or non-shatterable glass for automobiles. Its cost to-day is approximately the same as the heavier $\frac{1}{4}$-in plate.

Sizes of Polished Plate Glass. Plate glass is cut into stock sizes varying by even numbers from 6 by 6 in up to 144 by 200 in, or 138 by 208 in. Some larger sizes can be had by special manufacture.

Wire-Glass.* The introduction of this material has made it possible to secure fire-protection in many cases, without the necessity of disfigurement due to fire-shutters. Wire-glass is either RIBBED, ROUGH, FIGURED, or POLISHED PLATE, with wire embedded in its center during the process of manufacture.

The temperature at which the wire is embedded in the glass insures adhesion between the metallic netting and the glass, and the two materials become one and inseparable, so that if the glass is broken by shock, by intense heat up to about 1 700° F., or from other cause, it remains intact. It is this property of remaining intact that gives it its fire-retarding qualities. Although fire and water may cause cracks to spread throughout the glass, the wire holds the pieces so firmly that flames cannot pass through it. Many severe tests during actual fires have positively demonstrated the truth of the above claim. For warehouses and factories obscured surfaces are generally preferable; but for offices, or wherever clear transparent glass is desired, the POLISHED PLATE is nearly if not quite as acceptable as the same glass without the wire, the effect being the same as that obtained by looking through a window with a screen on the outside. Where FIRE-RESISTANCE is the desired feature, the following requirements should be satisfied. The thickness of the plate at the thinnest part should be not less than ¼ in, and the plane of the wire mesh should be midway between the two surfaces of the glass. No wire should be smaller than No. 24 Brown & Sharpe gauge. The unsupported surface of the glass should not exceed 720 sq in in any case and should be contained in a metal frame not larger than 5 by 9 ft between supports. As now manufactured by the continuous process, it is rolled in lengths up to about 12 ft and in thicknesses up to ½ in.

Figured Rolled Glass. This is a translucent or OBSCURED glass with a pattern stamped on one surface. As the molten metal is rolled out on the table, the design, cut into the table, imprints itself into the soft glass. This kind of glass has almost entirely supplanted the ordinary ground glass because of its greater cleanliness. There are several popular designs on the market, made by various manufacturers. Some of the designs in common use are known as MOSS, MAZE, SILVERITE and FLORENTINE. This glass is usually made ⅛ in thick and in large sheets from 24 to 42 in wide and from 8 to 10 ft long. MAZE, FLORENTINE and SILVERITE designs can be had either with or without the wire mesh in them. One important property of figured rolled glass is that of diffusing the light which passes through it.

Pressed Prism-Plate Glass. This is manufactured in different patterns and for different purposes and includes (1) Imperial Prism-Plate Ornamental Glass in five different patterns, (2) Imperial Prism-Plate Glass and (3) Imperial Skylight Prism Glass. The general description is as follows:

(1) Imperial Prism-Plate Ornamental Glass is plate glass ground and polished on one side. It is manufactured in plates, 54 by 72 or 72 by 54 in, can be cut into smaller sizes, and is made in five different stock patterns. It is used in modern mercantile, office and public buildings for partitions, transoms, doorlights, vestibule doors, ornamental ceiling-lights, bank-windows and other street-windows, and in all places where semiobscurity and ornamental

* See Glass and Wire-Glass, Article 5, Chapter XXII.

effect are desired. On account of its prismatic qualities it gives a strong diffusion of light for office-use where privacy is desired.

(2) Imperial Prism-Plate Glass. This is manufactured in large sheets, 54 by 72 or 72 by 54 in, and can be cut into smaller sizes. It is made in several different angles in order to obtain the proper diffusion of light for varying conditions. It is a plate glass, ground and polished on one side. There are no wires or bars to collect dirt and retard the light and it is very easily cleaned. It is used in the upper sashes of windows and in transoms, store-fronts, etc.

(3) Imperial Skylight Prism Glass. This is made in unit plates, 18 by 60 in, with a ½-in back, and conforms to the requirements of the Board of Fire Insurance Underwriters. It is used for skylights, roofs over areaways and in light-wells, etc. The possibility of leakage is lessened on account of the large-sized plates in which it may be obtained. These plates, however, can be cut into smaller sizes if required. It is particularly adapted for lighting the rear parts of stores and for railway-stations, sheds, etc.

Prism Glass, for glazing windows, skylights and sidewalk-lights, is now manufactured in a large number of forms in both prisms and sheets, and by several companies. This glass is made with sharp prisms which are glazed horizontally in the windows and by refracting the light throw it back horizontally into the rooms, adding very materially to the interior lighting. It is manufactured by several companies and can be procured from glass-jobbers in practically all the cities of the United States. Glass prisms for lighting are made of pieces of glass of standard dimensions, about 4 in square, with a smooth outer surface and an inner surface divided into a series of prisms. They are, in many cases, formed into plates by the process of electroglazing, the edges of the prism-lenses being welded together, so to speak, by a narrow line of copper which gives the desired stiffness and strength for use in large frames, and also an attractive appearance considered by some to be superior to ordinary leaded work. These prism-plates can be made in any desired size, but for very large surfaces two or more plates, divided by means of metal sash-bars, are generally used.

The commercial value of these prisms depends on that property of glass which causes what is known as REFRACTION. Prism-plates receive the light from the sky, not necessarily from the sun, and refract or turn it back into the room which is to be lighted. With an ordinary window the light from the sky, passing through the glass, strikes the floor at a point not very far distant from the window. As the color of the floor is usually dark, reflecting perhaps only one-tenth part of the light falling on it, the rear parts of the room receive only a small portion of the light which enters the window. For this reason it has been necessary to make very high stories for deep rooms, in order to light, even moderately, those parts which are at a distance from the window. When prisms are substituted for the common window-glass or plate glass, the rays of light as they enter the glass are refracted, and by employing prisms of the proper angle, the rays may be given almost any direction. Moreover, by utilizing different prisms in the same plate, some of the rays may be directed to the rear of the room while others are thrown so as to strike near the front. The prism-plates do not increase the quantity of light entering the window, but simply redistribute it, directing it into those portions of the room in which it is most needed. By thus changing the direction of light-rays a room with a low ceiling can be better lighted than when sheet or plate glass is used. To insure success in the lighting of interiors by means of prisms requires, however, a superior quality of glass, and careful scientific calculations and experiments, besides practical and attractive means of glazing and

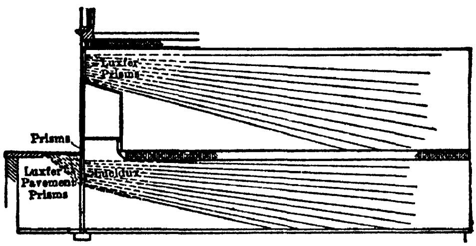
methods of installations. These requirements have been met by the several companies making these prisms and their products may be considered among the relatively new building materials. They have been very successfully applied to the lighting of dark rooms by daylight. The application of prisms to any particular building depends upon the surrounding conditions and requirements, each case requiring some special treatment; but in a general way the various appliances used in the installations may be divided into four classes as follows:

(1) Vertical Plates, which are set directly in the sashes in place of the ordinary window-glass. They are commonly used for the transom-lights of store-windows and the upper sashes of double-hung windows. They may also fill the entire window.

(2) Foriluxes, which are vertical prism-plates set in independent frames and placed in window-openings substantially flush with the face of the wall.

(3) Canopies, which are external prism-plates in independent frames, placed over window-openings and set at an angle with the vertical, a position similar to that of an ordinary awning.

(4) Pavement-Prisms, which are set in iron frames in the pavements or sidewalks, in place of the ordinary bull's-eye lights. In connection with the pavement-prisms, when a well-lighted basement is desired, vertical plates of prisms, hung below and opposite the pavement-lights, are often used. These hanging, vertical plates receive the light from the pavement-prisms, and again changing its direction, project it horizontally into the basement. This feature is illustrated in the figure here given, reproduced through the courtesy of the Luxfer Prism Company.



Refraction and Transmission of Light by Prisms

The canopies may be made either stationary or adjustable and may be employed in a variety of ways, combining the useful with the ornamental. The hanging, vertical plates lend themselves to a highly decorative treatment. In both the fixed and hanging vertical plates the prisms may be arranged to produce ornamental effects, and designs may be inwrought on the face of the prism-plates to correspond with the designs worked into the surfaces of the building and with the style of the entire façade. The prism-plates weigh no more, and often less, than plate glass of the same size, while they are much stronger in resisting wind-pressure, the action of hail and the impact of flying fragments. Although transmitting a very large amount of light, these prism-plates are not transparent in the ordinary sense, and may thus be used as screens to hide unattractive views or to prevent persons looking either in or out of a window. At the same time a maximum quantity of light is admitted. The prism-plates, owing to the stiff, durable manner in which they are united by the electro-glazing process, serve also as a fire-retardant or as a partial substitute for the ordinary iron fire-shutters. The copper glazing forms, as it were, a continuous rivet, which holds the individual prism-lights together, even after they have become badly cracked by the action of fire and water. The details of the various makes of prisms are too complicated to be set forth

in a few pages, but they are well described in the various handbooks and catalogues published by the different manufacturers. From a commercial point of view the special advantages of these systems of interior lighting are manifold. They transform rooms, particularly basements, otherwise too dark for occupancy, into income-producing spaces; in many buildings they do away with the use of light-shafts, thus saving a large amount of valuable floor-space; and in all large or deep rooms they effect a great saving in artificial lighting. Once installed, there is no cost for maintenance. The extent to which these prisms have been used by architects, in both new and old buildings, shows that they have had a decided influence upon commercial architecture.

Glass for Skylights. The glass ordinarily used for skylights is either ROUGH or RIBBED, PLAIN or WIRED. Since ¼-in wire glass is very close in price to the plain glass, the use of it has materially increased. A corrugated glass similar to corrugated iron or asbestos, ¼ in thick, is now being used very extensively for skylights, because it can be laid directly on the purlins without the necessity of a built-up frame, and, by this method of installation expansion and contraction can be taken care of so as practically to reduce breakage in skylight glass. The sizes of flat glass used depend largely upon the pitch of the skylight, small sizes being more desirable when the pitch is slight. The weight of rough or ribbed glass, with or without wire mesh, is approximately as follows:

Weight of Rough or Ribbed Glass

Thickness in inches	⅛	¼	⅜
Weight in pounds	2	3½	5

Glass for Mirrors. Mirrors are made by silvering one side of a sheet of polished plate glass. This is the only kind of glass suitable for making mirrors, because, unless the surface of glass is polished, the reflection is distorted. Originally, mirrors were made by the old-style process of pressing the glass by means of heavy weights onto mercury, backed by tinfoil, the affinity of mercury for tin forming an amalgam which protected the back of the mirrors and gave the reflection. This was a very slow and expensive process. Practically all of the mirrors made to-day are manufactured by what is known as the PATENT-BACK process, in which nitrate of silver is precipitated in a film over the surface of the glass, thus giving it the property of reflecting. This film is afterward covered and protected by shellac, varnish and paint. This modern method of manufacture has made it possible to supply mirrors in considerably less time, and at a very much lower cost, than when manufactured by the old-fashioned MERCURY-BACK process.

Ultra-violet Glass. Within the last few years glasses have been produced which will transmit ultra-violet rays of short wave length which are shut out by ordinary glass. It is these vital ultra-violet rays which tan the skin, improve blood and bone and develop increased resistance to disease. They are of inestimable value to children in affording protection against rickets. Certain makes of this type of glass may be had in sheet, polished plate, obscure and skylight glass. Owing to the variety of brands on the market, some of which are comparatively new, it would be well to see that manufacturers' claims are supported by controlled biological tests and actual experience in use as a means of establishing the efficiency of these glasses.

Anti-glare Glass. The increased use of glass in factory buildings, while it has resulted in greater daylight, has also brought about the problem of glare. In order to offset this condition, a glass has been devised known as ACTINIC GLASS, which intercepts a very large percentage of the ultra-violet (chemically active) and infra-red (heat) rays of the sun. This glass, when glazed, usually affords greater visibility because of its anti-glare properties. At present, it is made in only the ribbed and rough surfaces, 1/8 and 1/4 in thick, either with or without wire.

MEMORANDA ON ROOFING

Shingles. The best shingles are those made from cypress, cedar, redwood, white and yellow pine and spruce, in the order mentioned. Redwood, while perhaps not quite as durable as cypress, is less inflammable; sawed pine shingles are inferior to cedar, and spruce shingles are not suitable for good work.

Number and Weight of Cedar and Pine Shingles per Square of One Hundred Square Feet

Length, in	Assumed width, in	Weather or gauge, in	Number of shingles per square*	Weight per square		Number of nails per square	Weight of nails per square, lb
				Cedar, lb	Pine, lb		
14	4	4	900	210	233	1 800	4.50
15	4	4 1/2	800	200	222	1 600	4 00
16	4	5	720	192	213	1 440	3 60
18	4	5 1/2	655	197	218	1 310	3 28
20	4	6	600	200	222	1 200	3 00
22	4	6 1/2	554	203	226	1 108	2 77
24	4	7	515	206	229	1 030	2 58

* To allow for waste, add from 6 to 10%, the greater allowance being for the shorter shingles.

Sizes of Shingles. Cedar and redwood shingles as commonly sawed are 20 in in length, and cypress shingles usually from 20 to 24 in long, the longer ones allowing a greater exposure to the weather. Redwood shingles and the cedar shingles from the States of Washington and Oregon, which States furnish most of the shingles used west of the Mississippi, are 8/16 and 9/16 in thick at the butt; cypress shingles are usually sawed thicker. Those used in Boston are 9/16 in thick. Ordinary roofing-shingles are of random widths, varying from 2 1/2 to 14 and sometimes 16 in. They are put up in bundles, usually four bundles to the thousand. A THOUSAND common shingles means the equivalent of 1 000 shingles 4 in wide.

Dimension-Shingles are sawed to uniform width, either 4, 5, or 6 in. Dimension-shingles with the butt sawed to various patterns are also carried in stock.

On hip-roofs, or for four valleys, add 5% for cutting. On irregular roofs with dormer-windows, add 10%. It is claimed that redwood shingles will go farther than cedar shingles. With a rise to the roof of from 8 to 10 in to the foot, cedar shingles, or any shingles 16 or 18 in in length, should be laid from 4 to 4 1/4 in to the weather; with a rise from 10 to 12 in, from 4 1/4 to 4 3/8 in to the weather; and on steeper roofs they may be laid from 4 1/2 to 5 in. Red-

wood shingles may be laid ½ in more to the weather. Some authorities allow slightly greater exposures for these lengths. Where the longer shingles are used the exposure to the weather may be increased up to 7 in for the 24-in lengths. On walls cedar shingles are commonly laid 5 in to the weather, and redwood shingles 6 in.

Labor. An average shingler should lay 1 500 shingles in 9 hours on plain work; on irregular roofs with dormers, 1 000 per 9 hours.

Nails. It requires from 3½ to 4½ lb of threepenny or from 3½ to 6½ lb of fourpenny nails to 1 000 shingles, depending upon width and length of shingles.

Slate Roofs

Characteristics of Good Slate. A good slate should be both hard and tough. If the slate is too soft, however, the nail-holes will become enlarged and the slate will become loose. If it is too brittle the slate will fly to pieces in the process of squaring and holing and will be easily broken on the roof. "A good slate should give out a sharp metallic ring when struck with the knuckles; should not splinter under the slater's axe; should be easily HOLED without danger of fracture, and should not be tender or friable at the edges." The surface when freshly split should have a bright metallic luster and be free from all loose flakes or dull surfaces. Very few of the Vermont slates, however, have the metallic luster or ribbons. Some slates contain ribbons or seams which traverse the slate in approximately parallel directions. Slates containing soft ribbons are inferior and should not be used in good work where exposed to weather.

Color. The color of slates varies from dark blue, bluish black, and purple to gray and green. There are also a few quarries of red slate. The color of the slate does not appear to indicate the quality. All slate quarried in Maine is black as is also that quarried in Virginia, while that quarried in Pennsylvania and Maryland is also black but borders on dark blue and is advertised by some firms as dark blue or blue-gray. Slate quarried in New York State is red, of various tints, while that quarried in Vermont is of various colors, such as green, purple, variegated, etc. The red and dark colors were formerly considered the most effective but at the present time the greens are going on some of the largest and finest of the new residences. Some slates are marked with bands or patches of a different color, and the dark-purple slates often have large spots of light green on them.

Color Nomenclature. For the purpose of utilizing the basic natural colors of roofing slate available in large quantities for general usage, it is recommended* that the following color nomenclature be used by architects, contractors, engineers, and others in their specifications.

Black	Gray	Purple	Green	Red
Blue-black	Blue-gray	Mottled purple and green	Purple variegated	

These color designations shall be preceded by the word "unfading" or "weathering," according to the ultimate color effect that may be desired.

For roofs of special treatment certain quarries supply colors and combinations of colors other than those mentioned in the above list, and these should be regarded as "specials."

* Simplified Practice Recommendations, R14–28. Bureau of Standards.

Grading of Slates. The Monson, Me., slates and Brownville, Me., slates are graded as follows: No. 1. Every sheet to be full $\frac{3}{16}$ in thick, both sides smooth and all corners full and square. No pieces to be winding or warped.

No. 2. Thickness may vary from $\frac{1}{8}$ to $\frac{1}{4}$ in, all corners square, one side generally smooth, one side generally rough, no badly warped slates.

The Bangor, Pa., slates are graded.

No. 1 Clear. A pure slate without any faults or blemishes.

No. 1 Ribbon. As well made as No. 1 Clear, except that it contains one or more RIBBONS (a black band or streak across the slate), which, however, are high enough on the slate to be covered when laid, thus presenting a No. 1 roof.

No. 2 Ribbon. This contains several RIBBONS, some of which cannot be covered when laid.

No. 2 Clear. A slate without RIBBONS, made from rough beds.

Hard Beds. A clear Bangor slate, not quite as smooth as No. 1 Clear, but much better than No. 2 Clear.

Ordinary Bent Slate. A smooth slate similar to No. 1 Clear, but bent at a radius of about 12 ft.

* The art of splitting slate blocks consists in progressively reducing resultant halves until the desired roofing-slate thickness has been reached or approximated. This hand-wrought characteristic appeals to architects and owners. It is not a simple matter to control precisely the splitting of this natural rock, nor can a uniformity of thickness throughout be assured. The recommended range of thicknesses to be aimed at by operative splitters will meet all normal requirements and will insure the maximum of economy in the utilization of the many sizes of quarried blocks.

† It is customary to regard a thickness falling between two standard thicknesses as a "special," and it is the practice to base the price of the "special" upon the greater of the two standard thicknesses.

‡ For thicknesses $\frac{1}{2}$ in and more, it is not generally considered practicable to use lengths that are less than 16 in, although for roofs of special treatment it may be done in small quantities. In carrying out a desired design on special roofs, it is sometimes necessary to make shingles longer than 24 in, in which case the thicker slates are used.

NOTE.—Where large quantities of thick slates are required of the shortest practical length, one or more of the next longer slates should be permitted for most economical utilization of material from the quarry.

Dimensions of Slate Shingles for Flat Roofs

[Each size split to following thicknesses: For ordinary service, $\frac{3}{16}$ in; for promenade and extraordinary service, $\frac{1}{4}$ in and $\frac{3}{8}$ in]

6 by 6	10 by 6	12 by 6
6 by 8	10 by 7	12 by 7
6 by 9	10 by 8	12 by 8

Nail-Holes. The standard practice is to punch two nail-holes in all slates.

Dimension Nomenclature.* COMMERCIAL STANDARD THICKNESS (that is, average or basic). The terms "$\frac{3}{16}$-in slate," "full $\frac{3}{16}$-in slate," or "not less than $\frac{3}{16}$-in slate" indicate a desire for a hand-picked selection, regardless of the added labor and cost. "Commercial standard" is the quarry run of production and shows tolerable variations above or below $\frac{3}{16}$-inch. For the thicker slates, however, reasonable plus tolerances only are permissible; thus, a $\frac{1}{4}$-in slate must be a full $\frac{1}{4}$ in or thicker.

Laying. Slates are laid either on a board sheathing (rough, or tongued and grooved) covered with tarred or water-proof paper or felt, or on roofing-laths from 2 to 3 in wide and from 1 to $1\frac{1}{4}$ in thick, nailed to the rafters at distances apart to suit the gauge of the slates. Each slate should lap the slate in the second course below, 3 in. The slates are fastened with two threepenny or fourpenny nails, one near each upper corner. For slates 20 by 10 in or larger, fourpenny nails should be used. Copper, composition, tinned, or galvanized nails should be used. Plain-iron nails are speedily weakened by rust, and they break and allow the slates to be blown off. On iron roofs slates are often placed directly on small iron purlins spaced at suitable distances apart to receive them, and fastened with wire or special forms of fasteners. THE GAUGE of a slate is the portion exposed to the weather, which should be one-half the remainder obtained by subtracting 3 in from the length of the slate. Roofs to be covered with slate should have a rise of not less than 6 in to the foot for 20-in or 24-in slates, or 8 in for smaller sizes An experienced roofer will lay approximately 3 squares of slate in 8 hours.

Elastic Cement. In first-class work, the top course of slate on the ridge, and slate for from 2 to 4 ft from all gutters and 1 ft each way from all valleys and hips, should be bedded in elastic cement.

Flashings. By FLASHINGS are meant pieces of tin, zinc, or copper laid over slate and up against walls, chimneys, copings, etc.

Counterflashings are of lead or zinc, and are laid between the courses in brick, and turned down over the flashings. In flashing against stonework, grooves or reglets often have to be cut to receive the counterflashings.

Closed and Open Valleys. A closed valley is one in which the slates are worked tight to valley line, mitered and flashed in each course and laid in cement. In such valleys no metal can be seen. Close valleys should only be used for pitches above 45°. An open valley is one formed of sheets of copper or zinc 15 or 16 in wide, over which the slates are laid.

Old English Method of Laying Slates. This method of laying slate involves the use of different shades of colored slates in graduated courses and in random widths, beginning at the eaves, for example, with slates 28 in long and $1\frac{1}{4}$ in thick, and using the different thicknesses from $1\frac{1}{4}$ to $\frac{3}{8}$ in, in shorter lengths, in working upward on the roof. The use of this kind of work for

* Simplified Practice Recommendations, R14–28, Bureau of Standards.

roofs has increased in recent years and the method possesses vast possibilities for carrying out architects' ideas for varied artistic effects. The slates are made with rough-cut edges in all thicknesses from $\frac{3}{16}$ to $1\frac{1}{2}$ in, in a combination of the same or various shades carefully selected in such proportion as to produce the best possible harmony, when laid. As all of these colors and shades are unfading, the WEATHERED effect is obtained at once and is permanent. These slates are made not only in usual sizes, but in the OLD ENGLISH STYLE, to be laid in graduated courses of different lengths and in random widths. Architectural or graduated roofing-slates should be specified to secure the light-and-shadow effect, and it is of the utmost importance to specify the thickness desired, as the price is the same for all sizes, while the cost varies according to thickness. When graduated courses are desired, specifications should call for the number of courses to be laid in each length and thickness beginning at the eaves courses, where the thickest slates are used in the largest sizes, sometimes 30 or even 36 in in length, and working upward on the roof with the shorter lengths and thinner slates to the ridges where the smallest sizes and thinnest slates are used. To secure a rough effect at minimum cost, specifications should call for textural or graduated roof, slates to be fully $\frac{1}{4}$ in thick with rough cut edges and graduated courses in sizes ranging from 24 by 16 to 14 by 7 in, with punched nail-holes. To secure the best rough effect, specifications should call for eaves-courses not less than $\frac{3}{4}$ in thick, stating the thickness desired for the eaves, and the number of courses desired in each length and thickness. Among the good specimens of the Old English style of roofing may be mentioned the buildings of Princeton University for the Graduate College, where different shades of unfading-green slates are used in thicknesses running from $1\frac{1}{4}$ in at the eaves to $\frac{3}{8}$ in at the ridge.

Measurement. Slates are sold by the SQUARE, by which is meant a sufficient number of slates of any size to cover 100 sq ft of surface on a roof, with 3 in of lap, over the head of those in the second course below. The square is also the basis on which the cost of laying is measured. "Eaves, hips, valleys and cuttings against walls or dormers are measured extra; 1 ft wide by their whole length, the extra charge being made for waste material and the increased labor required in cutting and fitting. Openings less than 3 sq ft are not deducted, and all cuttings around them are measured extra. Extra charges are also made for borders, figures, and any change of color of the work and for steeples, towers, and perpendicular surfaces."

Weight. Slate roofing $\frac{3}{16}$ in thick will weigh on the roof about $6\frac{1}{2}$ lb per sq ft, and if $\frac{1}{4}$ in thick, $8\frac{3}{4}$ lb, the smaller sizes weighing the most on account of the lap. The actual weight of a square foot of slate $\frac{1}{4}$ in thick is 3.63 lb. A cubic foot of slate weighs approximately 175 lb. The average shipping weight for No. 1, $\frac{3}{16}$-in slates, is approximately 725 lb; for $\frac{1}{4}$-in slates, 1 000 lb; for $\frac{1}{2}$-in slates, 2 000 lb, etc.

Roofing-Tiles

General Notes on Roofing-Tiles. The term ROOFING-TILE is commonly understood to refer to exterior roof-covering made from clay in units of various shapes and laid with overlapping edges. Clay or terra-cotta roof-tiles have long been very largely used in Europe, where their cost is much less than in America. Since the year 1893 the advance here in the character and extent of roofing-tile has been marked and rapid. This material can now be had at much lower prices than formerly prevailed, and the result has been that thou-

sands of squares of terra-cotta tiles have been placed on shops and factories which would under former conditions have been covered with slate or metal. There are so many patterns of roofing-tiles that it is impossible here to enter into a description of them. Of the various patterns, those which interlock are considered, from a practical standpoint, to make the most satisfactory roof.

Laying Roofing-Tiles. Roofing-tiles have been laid directly on a porous book tile or concrete base or on a sheathed surface over such base, or they have been fastened to stripping over the sheathing or wooden or steel purlins by means of copper wires. When thus fastened by wires, the joints were usually pointed on the under side after they were laid, to prevent the entrance of dust or dry snow. Tiles of the older patterns were nailed to the sheathing, but later on this method was superseded by the practice of fastening with copper wires from pierced lugs near the lower ends of the tiles. The best modern method, however, seems to be the one involving a solid continuous base for the roofing-tiles, whether or not purlins are used. "Such purlins should be filled in between either with book tiles or a concrete base and felt should be laid thereon. The book tiles, if used, should be of a porous quality. Instead of regarding the nailing of tiles as a defective method, we have returned to it as the only proper method of fastening tiles and have eliminated the stripping of sheathed roofs and the use of copper wires. Such methods would do in some portions of central Europe where the winds and other climatic conditions are not severe, but through a twenty-five years' experience in the varied climatic conditions of the United States, we have found that the nailing of tiles with copper nails is the only satisfactory method of application. We have also found that a roof should be sheathed and covered with a good asphaltum-felt to prevent wind-suction." * Roofing-tiles weigh from 750 to 1 200 lb per square of 100 sq ft.

Specifications for Tile Roofing

The following specification† contains valuable suggestions for the proper laying of tile roofs:

All pitched roofs shall be covered with (——) tiles with fittings suitable for each pattern unless otherwise selected by the architect. The tiles as specified above are to be hard-burned, of red color, and in accordance with samples deposited in the office of the architect.

(1) Preparation of Roof. Before the roofer is sent for, the owner or general contractor is to construct the roofs in strict accordance with the plans, sheath the roofs TIGHT, have all chimneys and walls above the roof-line completed, have all vent-pipes put through the roofs, furnish all strips of required width used under hip-rolls, furnish all 1½ by ⅞-in cant-strips used under the tiles at the eaves and have all the scaffolding ready for the roofers' use. The metal-contractor is to have all gutters in place on the roof (gutters, whether box, hanging or secret gutters, are to extend over the roof-sheathing and cant-strips, and run under the felt and tiles at least 8 in) and is to have in place, also, all valley-metal, the width of which is to be not less than 24 in, with both edges turned up ¼ in through the entire length of the valley. The valley-metal is to be fastened with clips and never nailed or punctured in any manner. The valley-metal is to be laid over one layer of felt running lengthwise the entire distance of the valley. The metal contractor is to have in readiness all

* Quoted by permission from data on roof-tiling, by the Ludowici-Celadon Company, Chicago, Ill.

† Prepared from data furnished by the Ludowici-Celadon Company, Chicago, Ill.

flashing-metal used alongside and in front of dormers, gables, skylights, towers and perpendicular walls, and around vent-pipes and chimneys, and is to place the same after the arrival of the tile-roofer and under his direction.

(2) Laying the Felt. After the roofs have thus been prepared to receive the felt and tiles, the tile-roofer is to cover the sheathing of the roofs with one thickness of asphalt roofing-felt weighing not less than 30 lb to the square, laying the same with a 2½-in lap and securing it in place by capped nails. The felt is to be laid parallel with the eaves, lapped over all valley-metal about 4 in and laid under all flashing-metal about 6 in.

(3) Laying the Tiles. The roof having thus been prepared, the tile-layer is to fasten the tiles with copper nails. The roofer is to see that the tiles are well locked together and that they lie smoothly, and no attempt is to be made to stretch the courses. The tiles are to be laid so that the vertical lines are parallel with each other and at right-angles to the eaves. The tiles that verge along the hips are to be cut close against the hip-boards, and a water-tight joint made by cementing cut hip-tiles to the hip-boards with elastic cement. Each piece of hip-roll is then to be nailed to the hip-board, and the hip-rolls are to be cemented where they lap each other. The interior spaces of hip-rolls and ridge-rolls are not to be filled with the pointing-material.

Sheet-Metal Tiles. Roofing-tiles stamped from sheet steel, plain or galvanized, and also from sheet copper, in imitation of clay tiles, are made by several manufacturers and have been extensively used for factories and buildings of secondary importance. The first cost of these tiles, except those made of copper, is much less than that of clay tiles and they do not require as heavy roof-framing. Tin or galvanized-iron tiles, however, must be painted every few years, so that for a long period of years they probably cost as much as clay tiles and more than slate.

Tin Roofs

The Sheets. Roofing-plates are made of soft steel of various special analyses, or wrought iron (more commonly of the former), covered with a mixture of lead and tin, and are designated TERNE-PLATES, in distinction from plates coated only with tin and therefore called BRIGHT TIN. Roofing-plates are coated by two methods. (1) The original method of coating the plates consisted in dipping the black plates by hand into the mixture of tin and lead, and allowing the sheets to absorb all the coating that was possible; and at least one brand of roofing-tin is still made by this process. (2) The other process, by which the majority of roofing-plates are now made, is known as the PATENT-ROLLER-PROCESS, by which the plates are put into a bath of tin and lead, and are passed through rolls. The pressure of these rolls leaves on the iron or steel a thickness of coating which, to a great extent, determines the value of the plates. These rolls can be adjusted to leave a relatively large amount of coating on the plate, an ordinary coating, or a very scant coating. The heavier the coating the more valuable the plate. Some makers employ a variation of this patent process, by which the plates are given an extra dip, by hand, in an open pot, to give a HAND-DIPPED FINISH.

Brands. The best roofing-plates always have the BRAND stamped on them, and as the manufacturers have a pecuniary interest in keeping up the reputation of these brands, the only way of being sure of a good tin roof is to specify a brand of tin that has a reputation for quality and durability. Machine-made plates are usually stamped with the weight of coating per box of 112 sheets, 28 by 20-in size.

Sizes of Sheets. The common sizes of tin plates are 10 by 14 in and multiples of that measure. The sizes generally used are 14 by 20 in and 28 by 20 in. The larger size is the more economical to lay, and hence roofers prefer to use it; but for flat roofs the 14 by 20-in size makes the better roof.

Thicknesses of Sheets. Terne-plates are made in two thicknesses, IC, in which the iron body weighs about 50 lb per 100 sq ft, and IX, in which it weighs 62½ lb per 100 sq ft. For roofing, the IC, or lighter weight, is to be preferred, because the seams do not contract and expand as much as they do when the thicker plates are used. For spouts, valleys and gutters, however, IX plates should always be specified, and should preferably be used for flashings, as they are stiffer and less liable to be dented or punched. The thickness of the iron does not add to the durability of the plates, as this depends entirely upon the tin coating.

Weights of Sheets. The standard weight of 14 by 20-in IC terne-plates is 107 lb for 112 sheets, the number usually packed in one box, and of 14 by 20-in IX sheets, 135 lb. The 28 by 20-in sheets should weigh just twice as much. The black sheets, before coating, should weigh, per 112 sheets, from 95 to 100 lb for IC, 14 by 20-in sheets, and from 125 to 130 lb for IX, 14 by 20-in sheets. The difference between the weights of the black sheets and finished sheets is the weight of the tin. A heavily coated tin should weigh from 115 to 120 lb per 112 sheets for IC, 14 by 20-in sheets, and from 145 to 150-lb for IX, 14 by 20-in sheets. The 28 by 20-in sheets should, of course, weigh twice as much.

The Roof. Roofs of less than one-third pitch are made with FLAT SEAMS and should preferably be covered with 14 by 20-in sheets rather than with 28 by 20-in sheets, because the larger number of seams stiffens the surface and helps to prevent buckles and rattling in stormy weather. For a flat-seam roof, the edges of the sheets are turned ½ in, locked together and well soaked with solder. The sheets are fastened to the sheathing-boards by cleats spaced 8 in apart and locked in the seams. Two 1-in barbed and tinned-wire nails are used in each cleat. No nails should be driven through the sheets. The seams must be made with great care and sufficient time taken to properly SWEAT the solder into the seams. Steep tin roofs should be made with STANDING SEAMS and with 28 by 20-in sheets. The sheets are first single-seamed or double-seamed and usually soldered together, preferably end to end, into long strips that reach from eaves to ridge. The sloping seams are composed of two UPSTANDS, interlocked at the upper edge, and held to the sheathing-boards by cleats. The standing seams are usually not soldered but simply locked together with the cleats folded in about 1 ft apart. Nails should be driven into the cleats only. The use of acid in soldering the seams of a tin roof should be carefully avoided as acid coming in contact with the bare iron on the cut edges and corners, where the sheets are folded and seamed together, causes rusting. No other soldering-flux but good rosin should ever be used.

Durability of Tin Roofs. A tin roof of good material, properly put on, and kept properly painted, will last from forty to fifty years, or longer. All traces of rosin left on the roof should be removed as soon as the tin is laid and soldered, and one coat of paint should be applied promptly; a second coat should follow two weeks after the first. One or more layers of felt or water-proof paper should be placed under the tin, to serve as a cushion, and also to deaden the noise produced by rain striking the tin. The durability of tin roofing, and especially of tin gutters, valleys and flashings, is generally increased by painting the tin on the back before laying. An excellent paint for tin roofs is composed of 10 lb of Venetian red, 1 lb of red lead and 1 gal of pure linseed-oil.

Maintenance of Tin Roofs. The tin roof should be given one coat of paint after it is laid and an additional coat of paint at four-year or five-year intervals should be amply sufficient to keep its upper surface in first-class condition as long as the building stands. With each painting the roof is fully restored to its original condition. Graphite and tar paints should be avoided on tin roofs. Metallic brown, Venetian red, red oxide or red lead, only, should be used as pigments, with pure linseed-oil. Tinned gutters should be swept clear of accumulations of leaves, dirt, etc., and if water has a tendency to lie in the gutters they should be painted yearly.

Number of Sheets Required to a Square. For FLAT-SEAM ROOFING a sheet of tin 14 by 20 in, with ½-in edges, measures, when edged or folded, 13 by 19 in, or 247 sq in; but its covering capacity when jointed to other sheets on the roof is only 12½ by 18½ in, or 231.25 sq in. The number of sheets to a square, therefore, equals 14 400 divided by 231.25 or 63, and an area of 1 000 sq ft requires 625 sheets. A box of 112 14 by 20-in sheets will cover, approximately, 180 sq ft. Sheets 28 by 20 in, when edged or folded, have a covering capacity of 490.25 sq in each. To cover 1 000 sq ft (10 squares) requires 294 sheets. For STANDING-SEAM ROOFING the locks require 2¾ in off the width and 1⅛ in off the length of the sheet. A 28 by 20-in sheet, with the seams on the long edges, will cover 463 sq in. To cover 1 000 sq ft requires 312 sheets.

How a Tin Roof Should be Laid *

The Slope of the Roof. If the tin is laid with a flat seam or flat lock, the roof should have an incline of ½ in or more to 1 ft. If laid with a standing seam, there should be an incline of not less than 2 in to 1 ft. Although tin is used on roofs of less pitch than this and on some which are almost flat, a good pitch is desirable to prevent the accumulation of water and dirt in shallow puddles. Gutters, valleys, etc, should have sufficient incline to prevent water from standing in them or backing up far enough to reach standing seams. Tongued and grooved sheathing-boards of well-seasoned dry lumber are recommended. Narrow widths are preferable, and the boards should be free from holes, and of even thickness. A new tin roof should never be laid over old tin, rotten shingles, or tar roofs. Sheathing-paper is not necessary where the boards are laid as specified above. If steam, fumes, or gases are likely to reach the under side of the tin, some good water-proof sheathing-paper should be used. Tarred paper should never be used. No nails should be driven through the sheets.

Flat-Seam Tin Roofing. When the sheets are laid singly, they should be fastened to the sheathing-boards by cleats, using three to each sheet, two on the long side and one on the short side. Two 1-in barbed-wire nails should be used to each cleat. If the tin is put on in rolls the sheets should be made up into long lengths in the shop, and the cross-seams locked together and well soaked with solder. They should be edged ½ in, and fastened to the roof with cleats spaced 8 in apart, and the cleats locked into the seam and fastened to the roof with two 1-in barbed-wire nails to each cleat.

Standing-Seam Tin Roofing. The sheet should be put together in long lengths in the shop, and the cross-seams locked together and well soaked with solder. They should be applied to the roof the narrow way, and fastened with cleats spaced 1 ft apart. One edge of the course is turned up 1¼ in at a right angle, and the cleats are installed. The adjoining edge of the next course is

* These suggestions are in accordance with the standard working specifications adopted by the National Association of Sheet Metal Contractors.

turned up $1\frac{1}{2}$ in, and these edges are locked, turned over and the seam flattened to a rounded edge.

Valleys and Gutters. These should be lined with IX tin, and formed with flat seams, the sheets being applied the narrow way. It is important to see that good solder, bearing the manufacturer's name, is used, that it is guaranteed one-half tin and one-half lead, new metals, and that nothing but rosin is used as a flux. The solder should be well sweated into all seams and joints.

Painting. All painting should be done by the roofer. The tin should be painted one coat on the under side before it is applied to the roof. The upper surface of the tin roof should be carefully cleaned of all rosin-spots, dirt, etc., and immediately painted. The approved paints are metallic brown, Venetian red, red oxide, and red lead, mixed with pure linseed-oil. No patent drier or turpentine should be used. All coats of paint should be applied with a hand-brush, and well rubbed on. A second coat should be applied two weeks after the first and a third coat one year later.

Caution. No unnecessary walking over the tin roof, or use of it for storage of materials, should be allowed at any time. Workmen should wear rubber-soled shoes or overshoes when on the roof. Wherever the slope is steep enough the tin should be laid with standing seams, which allow for expansion and contraction.

Sizes, Weights, Etc., of Roofing-Tin *

Roofing-tin is usually furnished in two sizes, sheets 14 by 20 in and 28 by 20 in, packed 112 sheets to the box. Target-and-Arrow tin is furnished in three thicknesses: IC thickness, approximately No. 30 gauge, U. S. Standard; IX thickness, approximately No. 28 gauge, U. S. Standard; 2X thickness, approximately No. 27 gauge, U. S. Standard, etc. Weight per 100 sq ft laid on the roof, about 65 lb for IC thickness.

Covering Capacity of Roofing-Tin

Flat-Seam Tin Roofing. The following table shows the quantity of 14 by 20-in tin required to cover a given number of square feet with flat-seam tin roofing A sheet 14 by 20 in with $\frac{1}{2}$ in edges measures, when edged or folded, 13 by 19, or 247 sq in, but its covering capacity when joined to other sheets on the roof is only $12\frac{1}{2}$ by $18\frac{1}{2}$ in, or 231.25 sq in. In the following table each fractional part of a sheet is counted a full sheet.

* The following tables of sizes, weights, covering capacities and costs are adapted from useful data compiled for the use of sheet-metal workers by the N. & G. Taylor Company, Philadelphia, Pa.

A box of 112 sheets 14 by 20 in laid in this way will cover 165 sq ft.

Standing-Seam Tin Roofing. The following table shows the number of 28 by 20-in sheets required to cover a given number of square feet with standing-seam roofing. The standing seams take $2\frac{3}{4}$ in off the width, and the flat cross-seams, edged $\frac{3}{8}$ in, take $1\frac{1}{8}$ in off the length of the sheet. The covering capacity of each sheet is, therefore, $26\frac{7}{8}$ by $17\frac{1}{4}$ in, or 463 59 sq in. In the following table each fractional part of a sheet is counted a full sheet.

A box of 112 sheets 28 by 20 in laid in this way will cover 360 sq ft.

Laying the Long or Short Way. Sheets 14 by 20 in can be laid either the long or short way. The best roof is made by laying the sheets the 14-in way; similarly, in using the 28 by 20-in sheets, they should always be laid the 20-in way, that is, with the short dimension crosswise

Tin in Rolls. For the convenience of roofers and for rush-orders, certain brands are put up in rolls 14, 20 and 28 in wide. Each roll contains 108 sq ft (about 63 lin ft, 28 by 20-in sheets laid 20 in wide). The tin is painted on one or both sides, as wanted, with an approved metallic brown paint. The seams are carefully soldered by hand, good 100 to 100 solder and rosin being used as a flux.

Slag or Gravel Roofing

The Ordinary Gravel Roofing over boards is formed by first covering the surface of the roof with dry felt (paper) and over this laying three, four, or five layers of tarred or asphaltic felt lapping each other like shingles, so that only from 6 to 10 in of each layer are exposed. In laying roofs over concrete the dry felts are omitted, a mopping of pitch (or a primary coat and mopping of asphalt) being placed directly over the concrete and the felts embedded therein.

Flashing. Walls, chimneys, curbs of skylights, etc., when of metal, are reinforced behind the metal base by flashing with three plies of felt set in separately, in hot pitch or asphalt, extending out over the roofing felts at least 4 in and up the vertical wall at least 6 in. When felt and plastic elastigum are used for base flashing, the same are set in separately, four trowel coats of plastic and three plies of felt, extending out over the roofing at least 6 in and up the vertical wall at least 10 in. The several layers of felt can be fastened to the walls at the top with metal or creosoted-wood nailing-strips well pointed up with plastic elastigum. Metal counter-flashings to protect the felt are better than wooden strips and should be used when possible. At the eaves and on all exposed edges, metal gravel-stops should be used. After nailing the metal base flashing or metal gravel-stops on the roof, they should be stripped over with two plies of felt, set in hot pitch, before slagging the roof.

A Better Method of Slag or Gravel Roofing is to lay two plies of tarred felt, lapping each other 17 in, and then spreading a coat of pitch over the entire roof. On this three more layers of felt are laid full mopped between and then coated with pitch poured from a dipper, into which the crushed slag or screened gravel is embedded.

Specifications for Pitch-Slag or Gravel Roofing. The following specification-notes * describe the latter method more in detail and also the materials that should be used to secure a first-class job. These roofs are most efficient and durable on comparatively flat inclines. The usual built-up roof consists of successive layers of saturated felt cemented together and surfaced with coal-tar pitch or asphalt, into which is embedded the gravel or slag. Tile is also used as a surfacing material. The saturants used in the felt are generally coal-tar or asphalt-compounds.

(1) Specification for Pitch-Slag or Pitch-Gravel Roofing Over Wooden Sheathing

This specification should not be used when the roof-incline exceeds 2 in to 1 ft.

Lay one thickness of sheathing-paper or unsaturated felt weighing not less than 5 lb per 100 sq ft, lapping the sheets at least 1 in.

Over the entire surface lay two plies † of tarred felt, lapping each sheet 17 in over the preceding one, and nail as often as is necessary to hold them in place until the remaining felt is laid.

* Condensed and adapted from the roofing specifications published by the Barrett Company and known, in their full form, as "The Barrett Specifications"

† In the Western States the number of "plies" is construed to mean the total number of layers, including dry as well as saturated felt, and the terms 3-ply, 5-ply, etc., are hereinafter used on that basis. In the Eastern States, 3-ply, 5-ply, etc., usually refers to the number of layers of saturated felt. The total number of layers should always be specified if there is any doubt as to the exact meaning of the term as used in the specifications.

Coat the entire surface uniformly with pitch.

Over the entire surface lay three plies of tarred felt, lapping each sheet 22 in over the preceding one and mopping with pitch the full 22 in on each sheet, so that in no place felt touches felt. Do such nailing as is necessary so so that all nails are covered by not less than two plies of felt.

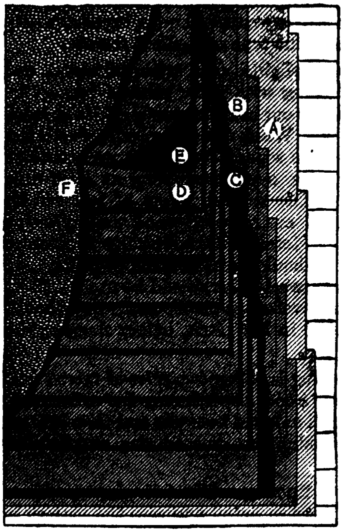

Diagram of Gravel or Slag Roofing on Wooden Sheathing

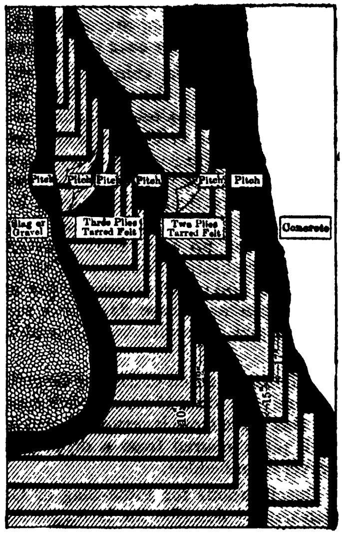

Diagram of Gravel or Slag Roofing on Concrete Base

Spread over the entire surface a uniform coating of pitch, poured from a dipper, into which, while hot, embed not less than 400 lb of gravel or 300 lb of slag to each 100 sq ft. The grains of the gravel or slag are to be from $\frac{1}{4}$ to $\frac{5}{8}$ in in size, and dry and free from dirt.

The roof may be inspected before the gravel or slag is applied, by cutting a slit not less than 3 ft long at right-angles to the direction in which the felt is laid. All felt and pitch is to bear the manufacturer's label.

(2) Specifications for Pitch-Slag or Pitch-Gravel for Roofing over Concrete

This specification should not be used when the roof-incline exceeds 1 in to the foot. When the incline exceeds 1 in to 1 ft the concrete must permit of nailing or nailing-strips must be provided.

Coat the concrete uniformly with hot pitch.

Over the entire surface lay two plies of tarred felt, lapping each sheet 17 in over the preceding one, mopping with pitch the full 17 in on each sheet, so that in no place felt touches felt.

Coat the entire surface uniformly with pitch.

Over the entire surface lay three plies of tarred felt, lapping each sheet 22 in over the preceding one and mopping with pitch the full 22 in on each sheet, so that in no place felt touches felt.

Spread over the entire surface a uniform coating of pitch, poured from a dipper, into which, while hot, embed not less than 400 lb of gravel or 300 lb of slag to each 100 sq ft. The grains of the gravel or slag are to be from ¼ to ⅝ in in size, and dry and free from dirt.

The roof may be inspected before the gravel or slag is applied, by cutting a sample at right-angles to the direction in which the felt is laid, not less than 4 in wide nor less than 3 ft long. After examination, the sample should be replaced and covered over with the same number of plies that constitute the roofing, each set in successively in hot pitch and each 4 in wider and longer than the preceding ply. All felt and pitch are to bear the manufacturer's label, and it is advantageous to have them also carry the Underwriters' label for materials as required for a Class A roof.

Notes on Slag and Gravel Roofing. The difference between slag and gravel roofing is that for the former crushed slag is used instead of gravel. The greater the number of plies of tarred felt, the greater the amount of pitch that it is practical to use, and it is the pitch that gives life to the roof. As there are several different weights and qualities of tarred felt, a specification should state either the minimum weight per 100 sq ft, single thickness (the most practical weight is from 14 to 16 lb), or some known quality, such as Barrett's "Specification Tarred Felt." Felt weighing less than 12 lb per 100 sq ft is not economical even on the cheaper work. To comply with the Barrett specification the materials necessary for each 100 sq ft of completed roof are approximately as follows:

Over boards	Material	Over concrete
108 sq ft	Sheathing-paper	None
80 to 85 lb	Specification tarred felt	80 to 85 lb
120 to 160 lb	Specification-pitch	180 to 225 lb
400 lb	Gravel	400 lb
300 lb	Slag	300 lb

In estimating felt, the average weight is practically 15 lb per 100 sq ft, single thickness, and about 10% additional is required for laps. In estimating pitch the weather-conditions and expertness of the workmen will affect the amount necessary for the moppings and for a proper embedding of the gravel or slag. As there are several qualities of pitch, a specification should either specify it by name, such as "Specification-Pitch" or "Straight-Run Coal-Tar Pitch," or in specifying asphalt-pitch, the brand or origin should be plainly defined. The use of an under-layer of sheathing-paper next to board-sheathing is mainly for the purpose of preventing any pitch which might penetrate the felt from cementing the roofing to the sheathing. It is also of value in preventing the drying out of the roof from below through open joints. Where a less expensive roof is desired, four plies or three plies of saturated felt may be used. With the four plies there should be used from 90 to 100 lb of pitch per 100 sq ft of completed roof; and with the three plies from 70 to 80 lb of pitch.

Durability of Slag or Gravel Roofs. These roofs, mentioned in the preceding paragraph, will last from five to ten years, or even longer, depending upon the quality of the materials used and the care with which they have been applied. Roofing put on strictly as provided for in the standard specifications will last twenty years or more, and if a tile surface is used, instead of gravel or slag, the roofing will last as long as the structure itself.

Resistance to Fire, Acid-Fumes, Etc. The fire-resisting properties of the slag or gravel roof are due principally to the incombustible material on the surface. It is claimed that the gravel or slag tends to prevent the successive layers of felt and pitch from burning and the whole mass has a blanketing influence on fires originating within the building. Some carefully conducted tests seem to indicate that gravel roofing protects a wooden roof better than tin. The general effect of a fire upon gravel roofing is to soften the pitch or asphalt in the roofing, to burn out the inflammable oil in them and to cause the residue to swell and form a porous, incombustible coke. This type of roofing is not attacked by corrosive gases or acid-fumes, and is used extensively on railroad-roundhouses and other structures where the conditions are particularly severe. Coal-tar or tar-oil should not be added to the pitch to soften it.

Bonded Guarantees. Bonded roofing offered by manufacturers of built-up roofing-material has no specific value unless the furnishings of the bond necessitate: (1) Delivery of high quality materials, (2) in such quantity as required by specifications covering proved long-lived roofs, (3) and applied exactly in accordance with such specifications, (4) by roofers of proved experience and integrity, (5) under the inspection supervision of the manufacturer's representative.

Asphalt-Gravel Roofing

Asphalt-Gravel or Asphalt-Slag Roofing differs from coal-tar roofing principally in the substitution of asphalt or asphaltic cement for the coal-tar pitch, for saturating the felt as well as for mopping and surface-coating. It is claimed that the oils of asphalt do not evaporate as quickly as do those of coal-tar pitch under ordinary temperatures and that, therefore, the flexibility and life of asphaltic felts and coatings are not as quickly destroyed. As a matter of fact, asphalt roofs, particularly on comparatively flat decks, have not proved as long-lived as some coal-tar roofs. In sections of the country where moisture is prevalent and water remains on the roof, erosion of the asphalt top coating has released the slag or gravel, thus permitting the weather-protection or fire-resistance value to be removed. Where the pitch of the roof is comparatively steep, however, the water runs off freely and the asphalt is less liable to slippage.

Specifications for Asphalt Roofing. The following specifications are for Warren's heavy standard Anchor-brand roofing. The manner of laying the felting differs from that ordinarily employed for coal-tar roofing.

(1) Specification for Asphalt-Gravel Roofing Over Wooden Sheathing

Cover the roof with two thicknesses of Warren's Composite roofing-felt, manila-paper side down, lapping each sheet 17 in over the preceding one, and securing with nails through tin discs about 2½ ft apart.

Over the entire surface of the Composite felt thus laid, mop an even coating of Warren's Anchor Brand roofing-cement, into which, while hot, lay two thicknesses of Anchor Brand felt, lapping each sheet 17 in over the sheet preceding, sticking these laps the full width with hot Anchor cement and securing with nails through tin discs not more than 20 in apart.

Over the entire surface of the felt thus prepared, spread an even coating of the cement, covering it immediately with a sufficient body of well-screened, dry gravel or crushed slag.

If the roofing is applied in cold weather the gravel or slag must be heated

Slag only should be used if the incline of the roof exceeds 3 in to the foot. All layers of felt must be turned up at least 4 in over battlement-walls, skylight-curbs, or any projections raised above the roof.

(2) Specification for Asphalt-Gravel Roofing Over Concrete

The concrete foundation is to be smooth and perfectly graded to carry the water to the outlets or gutters.

Over the entire surface of the concrete first mop a smooth, even coating of Eclipse Asphalt cement, into which, while hot, lay two thicknesses of Warren's Anchor Brand roofing-felt, lapping each sheet 17 in over the sheet preceding.

Mop back for the full width between the laps of the felt thus laid, with Warren's Anchor Brand roofing-cement.

Over the entire exposed surface of the felt mop an even coating of said Anchor cement, into which, while hot, lay two thicknesses of Anchor Brand felt, lapping each sheet 17 in over the sheet preceding, and sticking these laps thoroughly the full width with hot cement.

Over the entire surface of the felt thus prepared, spread an even coating of the cement, covering it immediately with a sufficient body of well-screened, dry gravel or crushed slag.

If the roofing is applied in cold weather, the gravel or slag must be heated.

Slag only should be used if incline of roof exceeds 3 in to the foot. On steep surfaces nailing-strips should be provided in the concrete, unless the latter is sufficiently soft to admit of nailing. All layers of felt must be turned up at least 4 in over battlement-walls and skylight-curbs, or any projections raised above the roof.

Roof-Incline. Asphalt-gravel or asphalt-slag roofing should not be applied to roofs which are steep enough to make the material run in hot weather. The manufacturers of various roofings will guarantee the permanency of their roofings for certain maximum slopes.

Prepared Roofing. There is a large number of PREPARED ROOFINGS or READY ROOFINGS, which are made by cementing together two, three, or more layers of saturated felt or felt and burlap and then coating the combination either with a hard solution of the same cementing material, or with hot pitch or asphalt into which is embedded sand or fine gravel. These roofings are commonly put up in rolls 36 in wide and are applied by lapping the strips 2 in with a coat of cementing material between, and nailing every 2 or 3 in with tin-capped roofing-nails. A sufficient quantity of cement, nails and tin caps is packed in the middle of the rolls. The particular advantage of these roofings is that no previous experience is required for laying them and no kettles are required; for this reason they are extensively used in the country, and on railroad-shops, factories, and mill-buildings. In cities there is no particular advantage in using them except for roofs that are too steep for coal-tar pitch. Many of these prepared roofings are as durable under ordinary conditions as the light-weight gravel roofs.

Corrugated Iron and Steel Sheets

Corrugated Sheets of iron and steel are very extensively used for the roofing and siding of mills, sheds, grain-elevators and warehouses. The best grades of corrugated sheets are now made of double-refined box-annealed iron or steel. The corrugations are usually made lengthwise of the sheet, either by passing them through rolls or by pressing the plain sheets in a press made to give the desired corrugations. It is claimed that the latter method gives the more per-

fect and uniform corrugations. The weight and thickness of the metal is represented by the gauge-number of the black sheets from which the corrugated sheets are made. The standard gauge for sheet iron and steel in this country is that established by act of Congress, March 3, 1893.

Gauges. The following table gives the weights and thicknesses of the different gauges, from No. 7 to No. 30, for flat BLACK SHEETS. The gauge extends from No. 7–0, ½ in thick, up to No. 40, 0.005469 in thick, but sheet steel is not commonly made thinner than No. 30, and above 3/16 in, the thickness is generally designated by fractions of an inch. Section 3 of the act of Congress provides that in the practical use and application of this gauge, a variation of 2½% either way may be allowed.

United States Standard Gauge for Sheet Iron and Steel

Number of gauge	Thickness		Weights	
	Approximate thickness in fractions of an inch	Approximate thickness in decimal parts of an inch	Weight per square foot in ounces, avoirdupois	Weight per square foot in pounds, avoirdupois

Galvanizing the Sheets adds approximately 2½ oz per sq ft to the above weights. The regular sizes of the corrugations are 2½, 1¼, 5/8 and 3/16 in, measured from center to center. Besides these sizes, 5-in, 3-in and 2-in corrugations are made by one or two corrugating companies. Corrugated sheets are carried in stock in 4-ft, 5-ft, 6-ft, 7-ft, 8-ft, 9-ft and 10-ft lengths. Sheets can be obtained as long as 12 ft at a cost of 5% extra. The 8-ft length, however, is most commonly used. The width of the sheets, as a rule, is 24 in between centers of the outer corrugations, so that the covering width is 24 in when one corrugation is used for the side lap. This applies to all sizes of corrugations, although some mills make wider sheets. The 2-in, 2½-in and 3-in corrugated sheets are made in all gauges from No. 16 to No. 28, the 1¼-in

corrugated sheets from No. 22 to No. 28, the 5/8-in corrugated sheets from No. 24 to No. 28 and the 3/16-in corrugated sheets in Nos. 26, 27 and 28 only. No. 28 gauge is the one commonly used for all purposes. The sheets are generally painted with a red mineral paint before shipping and galvanized sheets, also, can be obtained if desired. All corrugated sheets are sold by the square (100 sq ft), measuring the actual widths and lengths of the corrugated sheets.

Corrugated-Steel Roofing

Useful Data. For covering roofs, either 3-in, 2½-in, or 2-in corrugations should be used, the 2½-in being the most common size. The thickness or gauge depends upon the distance between the supports on which the sheets are laid.

Nos. 26 to 28 gauges should be laid on close sheathing, or strips not more than from 1 to 2 ft on centers. The maximum distances between supports for other gauges should be as follows.

For No. 24 gauge, from 2 to 2½ ft, center to center.

For Nos. 22 and 20 gauge, from 2 to 3 ft, center to center.

For No. 18 gauge, from 4 to 5 ft, center to center.

For No. 16 gauge, 5 to 6 ft, center to center

The least pitch which should be given to roofs that are to be covered with corrugated sheets is 3 in to the foot, and for trussed roofs it is not desirable to

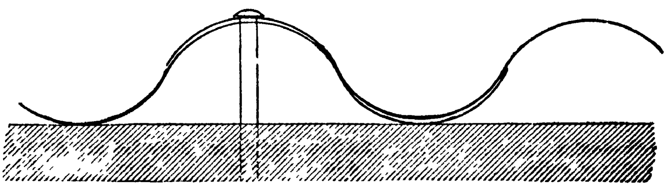

Fig. 1. Approved Method of Laying for Side Lap

have less than one-fourth pitch (6 in to the foot). When laid on a roof, corrugated sheets should have a lap at the lower end of from 3 to 6 in, according to the pitch of the roof. For a 1/3 pitch, a 3-in lap is used; for a ¼ pitch, a 4-in lap; and for a 1/8 pitch, a 5-in lap. For the side lap it is recommended that each alternate sheet be laid upside down and lapped as shown in Fig. 1. By this method, when water is blown through the first lap, it will stop and not pass the half lap, but run down and out at the end of the sheet. A great deal of roofing, however, is laid as in Fig. 2. In applying to sheathing or wooden strips, the sheets are secured by nailing through the tops of the corrugations, the nails being driven through every alternate corrugation at the ends, and about 8 in apart at the sides. When applied to iron or steel purlins, the side laps should extend over at least 1½ corrugations, and the sheets should be riveted together every 8 in on the sides and at every alternate corrugation at the ends. The Cincinnati Corrugating Company makes a patent edge-corrugation which makes a tight joint with a lap of only one corrugation. To fasten the sheets to the purlins, which are usually steel angles, cleats of band-iron, ¾ or 7/8 in wide, may be passed around or under the purlins and riveted at both ends to the sheets, as shown in Fig. 3. By contracting or pressing these cleats toward the web, a tight, secure fastening results, which allows for contraction and expansion of the sheets. Cleats, however, are generally used only with channel or Z-bar purlins. For angle-iron purlins, clinch-nails,

made of soft-iron wire, are commonly used, as shown in Fig. 4; they make very satisfactory fastenings.

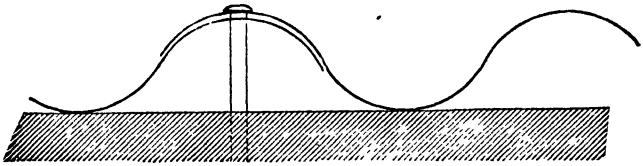

Fig. 2. Common Method of Laying for Side Lap

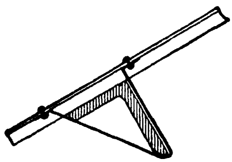

Fig. 3. Sheets Fastened to Angle-purlin by Band-iron Cleats

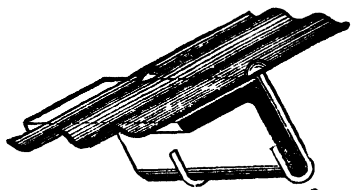

Fig. 4. Sheets Fastened to Angle-purlin by Clinch-nails

The following table shows the sizes of clinch-nails to be used with different sizes of angle-purlins and also the number of nails to the pound in each instance:

Purlin-angles	2×2 in	$2\frac{1}{2}\times3$ in	$3\frac{1}{2}\times3\frac{1}{2}$ in	$4\times4\frac{1}{2}$ in
Lengths of nails	4 in	5 in	6 in	7 in
Number of nails per pound	48	38	33	27

The nails should be placed through the TOP of every second or third corrugation. At the eaves of the building and along the edges of the ventilators special pains should be taken in fastening the roofing, as these are the places where the force of the wind is the greatest and where it tends to strip the roofing from the purlins. For these parts of the roof the best method of fastening is that shown in Fig. 5. These fastenings consist of strips of sheet iron about 2 in wider than the purlins, made of No. 12 iron and riveted to the purlins with $\frac{1}{4}$-in rivets spaced 10 in apart. To these strips the corrugated sheets are riveted, every

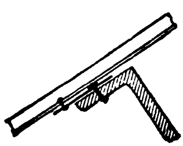

Fig. 5. Approved Fastening for Sheets at Eaves

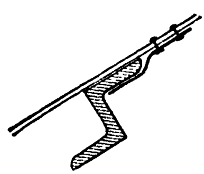

Fig. 6. Alternate Method of Fastening at Eaves

5 in or every two corrugates, with 6-lb rivets. The method of fastening shown in Fig. 6, also, answers very well and is less expensive.

In ordering corrugated sheets an allowance must be made for the laps. The following table gives the number of square feet necessary to cover one square of actual surface, using sheets 8 ft long. If shorter sheets are used, the allowance must be slightly increased.

Number of Square Feet of Corrugated Sheets to Cover 100 Square Feet of Roof

End-laps..	1 in	2 in	3 in	4 in	5 in	6 in
	sq ft	sq ft	sq ft	sq ft	sq ft	sq ft
Side lap, 1 corrugation. .	110	111	112	113	114	115
Side lap, $1\frac{1}{2}$ corrugations. . .	116	117	118	119	120	121
Side lap, 2 corrugations. .	123	124	125	126	127	128

Approximate Weights in Pounds of 100 Square Feet of $2\frac{1}{2}$-in Corrugated Sheets

Gauge..	No. 28	No. 27	No. 26	No. 24	No. 22	No. 20	No. 18	No. 16
Painted .	69	77	84	111	138	165	220	275
Galvanized. .	86	93	99	127	154	182	236	291

Anti-Condensation Lining. Wherever corrugated steel is laid on purlins with no sheathing or paper underneath, if the building is heated, moisture will invariably collect on the under side, and if the air in the building is warm and humid, considerable dripping will result. To prevent this dripping, it is necessary to protect the under side of the corrugated steel with paper or felt. This may be done by first stretching poultry-netting over the purlins, from eaves to ridge, and wiring the strips together at the edges. Over this should be laid one thickness of asbestos paper and one or two layers of saturated felt. The corrugated steel may then be fastened to the purlins in the usual way. The side laps may be secured by stove-bolts, with 1 by $\frac{1}{8}$ by 4-in plate washers on the under side, to support the lining.

Corrugated Steel Siding

For Siding, either the $2\frac{1}{2}$, 2, or $1\frac{1}{4}$-in corrugations are used. The $1\frac{1}{4}$-in size, however, makes the best appearance. For the laps, 1 in at the bottom and one corrugation at the sides are sufficient.

For Sheds, etc., the sheets may be nailed to cross-pieces cut in between the studs horizontally and spaced from 2 to 3 ft apart, the studs being from 3 to 4 ft on centers. For elevators, either cross-corrugated sheets or sheets not more than 32 in long should be used. The nails should be driven in the trough of each alternate corrugation, 2 in above the lower end of the sheet, which will be 1 in ABOVE the top end of the under sheet. This allows the sheet to slide 1 in in 32 in as the building settles, before the nail will strike the upper end of the lower sheet. The side lap should not be nailed.

Ceilings. For the ceilings of stores, stables, etc., $\frac{3}{16}$ or $\frac{5}{8}$-in corrugated sheets are much used; and the construction is an excellent one for this purpose.

Galvanized Iron. This term is commonly applied to all galvanized sheet metal. Formerly most of the galvanized sheets had a steel base, but since

about 1906 a nearly pure iron, called Toncan Metal, has been largely used for sheets of very fine quality. Galvanized sheets come in lengths of 6, 7 and 8 ft in United States Gauge-Nos. 14, 16, 18, 20, 22, 24, 26, 27, 28 and 30, and in widths of 24, 26, 28, 30 and 36 in for all gauges except No. 30, which is made only in widths of 24, 26 and 28 in Sheets of No 28 gauge are also made in widths of 32 and 34 in. The widths commonly carried in stock are 24, 28 and 30 in. Most of the galvanized iron used for cornices and ornamental work is No. 27 gauge. No. 28 is sometimes used for gutters and conductors.

Copper Roofing *

Copper possesses certain characteristics and physical properties which distinguish it from other metals used for roofing purposes. The greatest difference is in expansion and contraction. Copper has a higher coefficient of expansion than have iron and steel, and a lower one than have zinc and lead. This means that for a given temperature-variation there will be more movement in copper than in iron and steel and less than in zinc and lead. The standard length of copper sheets is 96 in. Sheets are stocked in widths in multiples of 2 in. The three usual methods of applying copper roof are: (*a*) RIBBED-SEAM METHOD, (*b*) STANDING-SEAM METHOD, and (*c*) FLAT-SEAM METHOD. The slope of roofs to be covered with flat-seam copper roofing should not be less than ½ in nor more than 3 in to the foot.

Fundamentals in Sheet-Copper Roofing and Flashing Construction.

(1) Use 16-ounce soft (roofing-temper) copper only.

(*a*) Do not use hard (cornice-temper) copper except for cornice work.

(*b*) Do not use lighter than 16-ounce copper.

"Soft" versus "Hard" Copper. Soft copper will give the most satisfactory results. Hard (cornice-temper) copper, though sometimes used for flashings and roofings, is not recommended. The soft sheet is, as can readily be understood, more easily workable, especially where bends, etc , are necessary.

Thickness of Copper Sheets for Roofs. It is not fair to a good material to use too thin a sheet. As copper does not corrode, there is no question of durability in the thinner gauges. Copper sheet weighing 1 lb per sq ft, commonly known as 16-ounce copper, is considered the minimum standard sheet strong enough to withstand extraneous injury. Thinner sheets do not give the best results.

(2) Prepare the laying surfaces carefully and see that it is smooth and even.

(*a*) All copper sheets should be laid on rosin-sized paper or asbestos felt.

(*b*) Sheathing boards should be ship-lap, tongued-and-grooved, or splined.

(*c*) All nail-heads should be set.

Roofing-Boards or Sheathing. It is recommended that ship-lap or tongued-and-grooved roofing-boards be used. All roof-sheathing should be well laid with even joints and secured at all bearings with heavy nails well set. Immediately after laying, the sheathing should be protected by covering it with paper as mentioned below. If possible the sheathing should be exposed to the weather at least 4 weeks before covering it with copper. The wood must be thoroughly dry and seasoned.

Paper over Sheathing. Good practice requires either the ordinary building paper or a rosin-sized or asbestos paper weighing about 6 lb per 100 sq ft.

* Taken from data furnished by the Copper and Brass Research Association, New York City.

On concrete roof-slabs paper is not essential, provided the surface be made smooth and even as outlined below.

Concrete Roof-Slabs. When copper is used over concrete the surface should be made smooth by a wash of neat cement. Elastic cement is sometimes used for this purpose. Cinder concrete should not be used in contact with copper. Where copper is used in this type of construction the concrete should be painted with a heavy coating of asphalt paint before the copper is applied. Wood battens or expansion inserts must be set in the concrete for fastening the cleats.

(3) Avoid sharp bends in copper sheets.

(*a*) Do not crease the sheets or bend them more than 90 degrees.

(*b*) Bend the sheets as little as possible before laying.

(4) Allow for movement at intersections of roof-planes by large loose-locked joints.

(*a*) Never carry a copper sheet more than 3 or 4 in over an angle.

(*b*) Break the sheet and lock it to the adjoining one by means of a loose- or double-locked joint. This allows room for expansion and contraction.

Expansion and Contraction. The temperature at the time the work is done must be taken into consideration by the contractor in allowing for expansion and contraction. A roof laid in July needs little rooom for expansion. It does, however, require ample provision for the contraction which comes with cold weather. The reverse is, of course, true when a roof is laid in cold weather, and under these circumstances the contractor must be careful to provide ample room for movement.

(5) Never nail copper sheets. Use cleats.

(*a*) By "sheet" is meant any piece over 12 in wide.

(*b*) Use two-nail cleats 1½ in wide and place them not more than 12 in apart.

(6) Use copper nails only—never iron or steel—for fastening strips and cleats.

(*a*) Flat-head, wire "slating," or "shingle," nails are preferable.

(*b*) Strip copper should be nailed along one edge only.

(*c*) Nails should be spaced 4 in maximum.

Cleats. Always secure the copper sheet by copper cleats, the cleats only being nailed to the roofing-boards, the battens or wood ribs. Never use nails of iron or steel to fasten copper at any place or under any circumstances. Galvanic action will quickly destroy the ferrous metal.

Copper and Other Metals. If possible, never use copper in contact with another metal, but if the plan of construction requires the use of iron or steel, by all means see that the iron or steel device is heavily tinned or that sheet lead is inserted between the copper and the other metal. The use of brass devices is recommended, especially for gutter and eaves-trough hangers.

(7) Make full-size joints and seams.

(*a*) Standing seams at least 1 in finished.

(*b*) Flat seams (locked) at least ½ in finished.

(*c*) Lapped seams at least 1 in finished.

(*d*) Double or copper-locked seams at least ½ in finished.

(8) Tin carefully and thoroughly.

(*a*) Use heavy tinning-coppers.

(*b*) Use enough tin to cover all the surface.

(9) Use rosin as a flux rather than acid.

(a) If acid is used, see that it is properly and thoroughly killed.

(10) Plenty of solder, well-flowed over, makes strong seams.

(a) Use the best half-and-half solder and lots of it.

(b) Heat the seam thoroughly.

(c) Heavy, hot coppers are best for this.

Cleaning. As soon as a portion of the roof is finished it should be carefully cleaned of all flux, scraps and dirt. Prominent signs should be displayed, where necessary, to prevent walking on the copper, and every reasonable precaution should be exercised to keep the roof tree from all foreign substances, such as mortar, scraps of lumber, paper, etc. As the development of the characteristic green patina of copper is very much retarded by dirt, flux, etc, too much emphasis cannot be placed on thorough cleaning. Accumulation of dirt means uneven, splotchy coloring.

Finish. Copper will develop a beautiful patina in a few months, owing to natural phenomena. When it is desired to obtain this finish immediately, it can be done by the use of the following methods: (1) Clean the copper by washing it thoroughly with a strong solution of soda and hot water to remove the grease acquired in the process of rolling. (2) Apply the following solutions:

(a) One pound of powdered sal ammoniac to 5 gal of water; dissolve thoroughly and let stand 24 hours. Apply to copper with a brush, covering every part. Let stand one day, and then sprinkle surface with clean water.

(b) Use a solution of ½ lb of salt to 2 gal of water. Apply in same manner.

(3) A dark copper finish can be obtained by the following method: Rub off the copper with cotton waste soaked in boiled linseed-oil. Touch up soldered seams with copper bronze.

Painting Copper. It is difficult to obtain a good bond between paint and copper. This is due to the grease and oil of the manufacturing process which is rolled into the fine pores in the surface of the sheets. Paint applied directly to untreated copper will not stand for any length of time, particularly when exposed to the weather. The surface must be thoroughly cleaned and roughened before the paint will adhere. This may be accomplished by washing the copper with a solution of 4 oz of copper sulphate in ½ gal of lukewarm water in a glass or earthen vessel, to which is added ⅛ oz of nitric acid. If the surface is still very smooth, additional roughening must be done by abrasives. Before painting, the surface must be carefully washed with clean water to remove the last trace of the solution and the paint must not be applied until the surface is thoroughly dry. Three coats of paint will give the best results. The first coat should be composed of 15 lb of red lead to 1 gal of raw linseed-oil with not more than ½ pt of oil drier The last two coats should be composed of 15 lb of white lead to 1 gal of raw linseed-oil with not more than 5% of oil drier and the necessary color.

White Lead. White lead in oil is a good substance for filling lock seams in copper work. It is simple to apply, is water-tight, and remains so a long time. White lead has been used on copper roofs, laid many years ago, both in this country and abroad. Notable among roofs of this type is that on the State House in Boston, Mass. This roof was laid in 1887–90 with leaded seams, and is apparently as tight to-day as it was forty years ago. The method of applying consists of smearing the edges of the sheets plentifully with white lead in oil and folding and locking them to form lock seams in the usual way. The viscous lead and oil completely fills the lock, making a water-stop. White lead used in this way has much to recommend it. It is cheaper

than soldering, and it is durable. On flat roofs where water backs up it is better to use solder, but on free-draining surfaces white lead can be used with every assurance of satisfaction. The proper lead to use is that composed of basic lead carbonate and boiled linseed-oil in paste form. It must be smooth and of putty-like consistency. Lumps will make uneven seams and prevent the locks from being completely filled. After the seams have been locked and malleted all excess lead should be carefully removed from the sheets.

Proportioning Gutters and Leaders. The chief consideration in designing gutters and leaders is to conduct the water running off a roof quickly and easily. To do this it is essential that (1) the gutter be large enough to conduct all the water to the outlet; (2) the outlet be large enough to accelerate the velocity of the water in the gutter when it enters the outlet.

A safe system to follow in mill building design is that of the American Bridge Company. Their specifications provide as follows:

Span of roof	Gutters	Leaders
Up to 50 ft	6 in	4 in every 40 ft
50 to 70 ft	7 in	5 in every 40 ft
70 to 100 ft	8 in	5 in every 40 ft

Hanging gutters shall slope 1 in in every 16 ft.

Progressive Steps in Designing Gutters and Leaders.

(1) Locate position of leaders.
(2) Compute area of roof drained by each leader.
(3) Compute size of leader.
(4) Compute size of gutters to supply leaders.

NOTES.

(1) Round leaders should not be less than 3 in in diameter.
(2) Rectangular leaders should not be smaller than $1\frac{3}{4}$ by $2\frac{1}{4}$ in.
(3) Gutters should not be less than 4 in wide.
(4) Gutters should have a fall of not less than 1 in in 16 ft.
(5) Scuppers should be provided for all roofs with a parapet wall built around them. This precaution prevents an overloading of the roof owing to stoppage of the outlet.
(6) All outlets should be provided with screens or strainers.

Built-In or Box Gutter-Linings of Copper. For best results in gutter linings the following practice is recommended.

(1) The design of the gutter should avoid sharp angles. The sides should slope as much as possible to approximate an arc. The inside edge of gutter should be at least 3 in higher than the outside edge. Gutters should be as shallow as possible.

(2) The gutter should be wood-lined to receive the copper.

(3) Sixteen-ounce soft (R.T.) copper sheets which have been crimped are excellent. Their length is optional up to 8 ft maximum; their width should not exceed 36 in.

(4) Longitudinal seams should be double-locked. This provides strength at the seam and with (3) allows plenty of opportunity for expansion.

(5) Seams should be well soldered.

(6) The junction with the roof flashing should be by a large loose-locked joint so placed as to need no solder to make it water-tight.

(7) If long sheets are used a double-cross seam should be used.

Scuppers. One of the most important points of roof-drainage design is often forgotten. This is proper provision for overflow by means of scuppers. A great many buildings have flat roofs enclosed by parapet-walls and inside drainage-systems. When the outlet becomes clogged, water collects on the roof and not only causes an overload, but may also work its way over the flashing and down into the building. On all roofs of this character—that is, where there is not ample provision for escape of the water when the leaders do not work, it is absolutely necessary to provide scuppers through the wall. These should be large enough to preclude any possibility of clogging (at least 4 by 12 in), and should be unobstructed in any way by screens, etc. When copper flashings are used, the scuppers are completely lined with copper and this lining is soldered to the base flashing, the counter-flashing being worked around the hole, or omitted at this point.

Galvanic Action in Roofing-Materials. Dissimilar metals, when in contact in the presence of an electrolyte, set up galvanic action which results in the deterioration of the most electropositive metal Starting with the most electropositive, the commercial metals are listed as follows

1. Aluminum (most electropositive)
2. Zinc
3. Steel
4. Iron
5. Nickel
6. Tin
7. Lead
8. Copper (most electronegative)

This means that when iron (or steel) and copper are in contact with an electrolyte present (which may be water), the iron is corroded. When copper and lead or tin are in contact, a tendency for similar action exists but it is very slight and produces practically no injurious results. This is because the difference in potential is much less and the corrosive action is negligible, especially where water is the electrolyte. Any possibility of galvanic action between copper and iron or steel should be carefully avoided by proper insulation. This insulation is effected in various ways, three of which are: (1) covering the steel member with asbestos, as is frequently done in skylight construction; (2) placing strips of sheet lead between the two metals, as when new copper gutters are placed in old iron hangers; and (3) heavily tinning the iron, as is often done with iron or steel gutter and leader-supports.

MEMORANDA ON TILING

Floor-Tiling and Wall-Tiling

Tile Floors are extensively used in the better class of buildings, and particularly in those portions which are used by the public, on account of their great durability, sanitary qualities and decorative effects. As a matter of fact, a good tile floor is also cheaper in the long run than a wooden floor if it is subject to much wear. The materials used for tiling floors are tiles made from different grades of clay, marble, slate, glass and rubber. Of these probably the most durable and sanitary are the vitreous clay tiles. For walls and wainscotings, glazed tiles, marbles and glass are extensively used.

Floor-Tiles. The following include some of the principal kinds of clay tiles:

(1) **Common Encaustic Tiles.** These belong to the cheapest grades, and are made of naturally colored clays, red, buff, gray, chocolate and black. These tiles are of a porous, absorbent nature and are used for common floors where sanitary requirements are not exacting.

(2) **Semivitreous Tiles.** These belong to a somewhat better grade than the first mentioned and are less porous and absorbent.

(3) **Vitreous Tiles.** These are the hardest tiles known, cannot be scratched by steel or sand, and are non-absorbent and thoroughly aseptic. They are used principally for floors requiring a perfect sanitary condition and are manufactured in white, blue, gray, green and pink colors of great delicacy.

(4) **Ceramic Tiles or Ceramic Roman Mosaic.** This material is made of VITREOUS clay in tesseral pieces representing the tesseræ of the Roman mosaics. It is made into regular tiles ranging from ½ to ¾-in squares and also in hexagonal shapes from ¾ in to 1 in in size. A rounded LOZENGE TILE is also manufactured to be laid in tesseral paving. (See, also, Flooring of Mosaic, Terrazzo, etc)
The material itself is of great hardness and well suited for work of a monumental or public character. The even and regular texture of the tesseræ admits the adoption of DAMASK DESIGNS which have become identified and associated with this material. The minuteness of the tesseræ admits of a great range in designing and the following of the architectural lines. The ceramic Roman mosaic is much preferred to mosaic consisting of natural marbles, because of the great variety in colors and its greater durability. The vitreous-clay tiles are impervious to attacks of any acids contained in the atmosphere, while marbles, especially, are subject to rapid disintegration caused by the sulphuric acid contained in the smoke-laden atmosphere of our cities.

(5) **Florentine Mosaics and Flint Tiles.** These are the largest and heaviest tiles manufactured in this country. They are either plain or inlaid and are in use especially in ecclesiastic work on account of their relation to mediæval application. The material is vitreous, annealed and tougher than it is brittle. It is also in use for exterior polychrome work.

(6) **Aseptic Tiles.** These are large, heavy and thoroughly vitreous tiles used for institute work. They are the only vitreous tiles of large size made in this country. As the tiles are large and generally of hexagonal shape, the joint-spaces are reduced to a minimum, and they are, therefore, especially adapted for hospitals, operating-rooms and wards for contagious diseases.

Enameled Tiles, Wall-Tiles and Mantel-Tiles. The following include some of the enameled tiles:

(1) **White Wall-Tiles.** These are glazed tiles for wainscots. They have a white, soft body and a surface covered with a clear glaze. The brilliancy of this glaze and its reflecting properties make the white wall-tiles especially desirable for dark passages.

(2) **Colored, Glazed or Enameled Tiles.** These tiles are about the same as the former in quality; the GLAZE or ENAMEL, however, is stained with metallic oxides, which produces a brilliant decorative effect.

(3) **Dull-Satin, etc., Finished, Enameled Tiles.** These are glazed tiles with a DULL or BLIND enamel-finish. The dull finish is produced either by sandblasting or by devitrifying enamels. It is principally used for quaint decorative effects in mantel-work.

(4) **Glazed Roman Mosaics.** This is a type of enameled tiling which has great decorative possibilities. It has the same tesseral texture as the ceramic floor-tiles and is readily applied to wainscots and mantel-work.

Setting of Tiles. Clay tiles are set in Portland-cement mortar as a rule, and flooring of this character should always be provided with a substantial

concrete base. Ceramic mosaics are sometimes laid on a flexible base. With this construction wooden floors can be provided with tile covering, and owing to the elasticity and lightness of the material, floors in elevators, boats and other ambulant structures can be safely tiled.

Marble Tiles, from 9 to 12 in square, have been extensively used for flooring, principally on account of their decorative effect. None of the marbles, however, is as hard and consequently as durable as the vitreous and ceramic tiles. When used, they should be 1¼ in thick and not over 12 in square, and should be bedded in cement on a concrete base. Marbles should not be used for flooring in hospitals, as they yield rapidly to the usual antiseptic floor-washes.

Slate, non-absorbent and not affected even by dilute mineral acids. It is frequently used as flooring and as a cover for wiring and pipe-trenches in the floors. As these often follow a wall, it may serve in the capacity of a border and as such be extended around the floor-space. Slate slabs for floors should be about 1¼ in thick.

Marbleithic Tiles or Slabs are made of small pieces or chips of marbles of irregular shapes, set in a backing of sand and Portland cement. After the cement has set, the top surface is rubbed until it becomes flat and smooth. Marbleithic resembles mosaic or TERRAZZO, except that it is laid in the form of tiles instead of being put down on the floor in a plastic condition. Much objection has been made to TERRAZZO because of the cracks which commonly occur in it, due to the slight settlements which are unavoidable in a new building. With tile floors of any material the joints allow for any slight movement of the floor-construction without causing visible cracks. By the process of manufacture, marbleithic is made much harder than it is possible to make mosaic floors that are laid in a plastic condition, so that they have a much better wearing surface. Marbleithic tiles are made of various colored marbles and in different sizes, shapes and patterns, so that a great variety of effects may be produced. Sanitary coved bases, stair-treads, and wainscotings, also, are made of this material.

Cast-Glass Tiles, while quite resistant to a blow when the polish is unbroken, will break very easily when the surface is scratched. All glass tiles should, therefore, be very thick and small or protected by metal framing.

Novus Sanitary Glass is a sanitary structural glass manufactured in all thicknesses from ½ in up to 2 in and in slabs of all widths and lengths up to 100 in in width and 180 in in length. It is made in various colors and designs and in the following finishes: natural-fire finish, hone, semipolished and polished. It can be worked and handled the same as marble, it is readily drilled and shaped to accommodate fixtures, etc., and is very handsome in appearance. It is impervious to discoloration and is non-crazing. These qualities make it especially desirable for floors, wainscoting, tables, shelves, etc., in all places where an absolutely sanitary condition combined with a pleasing appearance is required.

Interlocking Rubber Tiling

General Description. Interlocking rubber tiling, which, because of its being noiseless, non-slippery, and more comfortable to the feet than inelastic substances, has met with great favor for floors in banking-rooms, counting-rooms, vestibules, elevators, stairs, cafés, libraries, churches, etc. For elevators it is one of the most durable and practical floors that can be laid; it is also especially and peculiarly adapted for floors of yachts and steamships. The interlocking feature unites the tiles into a smooth, unbroken sheet of

rubber, unlimited in area. The tiles do not pull apart or come up, and each being distinct, almost any color-scheme can be employed, the tiles being made in a carefully selected variety of colors. The tiles are laid directly over the original floor, like a carpet, except that they are not fastened. Experience has shown that they are very durable. Each tile is 2⅜ in square and ⅜ in thick; 25.5 tiles are required to the square foot. Rubber nosing for stairs is made to interlock with the tiles.

Flooring of Mosaic, Terrazzo, etc.

Flooring of Mosaic Work is largely used. It is composed of small pieces of stone, marble, pottery or glass, usually laid in some ornamental design or pattern. A bed of concrete is first laid and the small pieces of the material used set in a floating of cement and made from ½ to 1 in thick. When cubes of varicolored marble are used, pressed into the cement mortar, it is called ROMAN MOSAIC. A somewhat cheaper flooring is made by spreading marble chips of irregular shape over the surface of the cement, pressing them into it with plasterers' floats and rolling them with iron rollers. This is called TERRAZZO MOSAIC. The following is from the specifications for the new Field Museum, Chicago, Ill., D. H. Burnham, architects: "Filling under terrazzo shall be composed 1 part cement, 2 parts sand and 4 parts brick. Before concrete filling commences to set spread a ¾-in wearing surface composed of marble chips with only enough neat Portland cement to firmly unite the pieces. Trowel and roll, and after the mortar has set, rub the terrazzo to a smooth, even surface and wash clean."

ASPHALTUM

Bitumen, Asphaltum, Asphalt. " Bitumen is the name used to denote a group of mineral substances, composed of different hydrocarbons, found widely diffused throughout the world in a variety of forms which grade from thin volatile liquids to thick semifluids and solids, sometimes in a free or pure state, but more frequently intermixed with or saturating different kinds of inorganic or organic matter. To designate the condition under which bitumen is found, different names are employed; thus the liquid varieties are known as NAPHTHA and PETROLEUM, the semifluid or viscous as MALTHA or MINERAL TAR, and the solid or compact as ASPHALTUM or ASPHALT."

Asphaltum is found in extensive beds or lake-like deposits on both continents; the most notable of these are the PITCH lakes on the island of Trinidad, and at Bermundez, Venezuela. It is also found saturating the limestone and sandstone formations in certain localities. Deposits of very nearly pure asphaltum are found in Utah, Mexico, Cuba, and various parts of the United States. ELATERITE, GILSONITE and WURTZILITE are varieties of very nearly pure asphaltum.

Asphaltic Roofing-Materials are manufactured principally from Trinidad asphalt. These deposits have also been the main source of supply for the asphaltum used in street-paving in the United States.

Rock-Asphalt. The term ROCK-ASPHALT is commonly used to designate the material obtained from the bituminous limestone deposits at Seyssel and Pyrimont, in the valley of the Rhône, France, in the Val-de-Travers, canton of Neuchâtel, Switzerland, and at Ragusa, on the island of Sicily. It is extensively employed for paving purposes throughout Europe, and is considered to make a much more durable pavement than can be made with asphaltum.

Rock-asphalt is prepared for shipment in two forms: (1) COMPRESSED ASPHALT BLOCKS, which are used for paving in much the same way as stone blocks, and (2) MASTIC-ASPHALT, which is put up in cakes of varying shape, generally bearing the manufacturer's trade-mark.

Mastic-Asphalt. In the Eastern States MASTIC-ASPHALT is used for floors of cellars, stores, breweries, malt-houses, hotel-kitchens, stables, laundries, conservatories, public buildings, carriage-factories, sugar-refineries, mills, rinks, etc., and for any place where a hard, smooth, clean, dry, fire-proof and water-proof, odorless and durable covering of a light color is required, either in the basement or upper stories. It can be laid over cement concrete, brick, or wood, in one sheet without seams; also over cement concrete for roofs for fire-proof buildings. For dwelling-house cellars, especially on moist or filled land, this material is especially adapted, being water-tight, non-absorbent, free from mold or dust, impervious to sewer-gases, and for sanitary purposes, invaluable. Mastic-asphalt is also valuable for DAMP-COURSES over foundations, and for covering vaults and arches under ground.

Asphalt Floors and Pavements. For floors of cellars, courtyards, etc., laid on the ground, a base of cement concrete 3 in thick should first be laid; and over this a layer of asphalt from $\frac{3}{4}$ to $1\frac{1}{2}$ in thick, according to the use to which it is to be put. For ordinary cellar-floors, the asphalt need not be more than $\frac{3}{4}$ in thick; for yards on which heavy teams are to drive, it should be $1\frac{1}{2}$ in thick. In specifying asphalt pavement, both the thickness of the concrete and of the asphalt should be given; it should also be remembered that ASPHALT PAVEMENT does not include the CONCRETE FOUNDATION unless so specified. In laying asphalt over planks or boards, a layer of stout, dry, but not tarred, sheathing-paper should first be put down and the asphalt laid on this. Asphalt floors for stables should be at least 1 in thick. Architects and owners desiring to employ ROCK-ASPHALT for any of the above purposes should be careful to secure the genuine VAL-DE-TRAVERS, SEYSSEL, or SICILIAN ROCK-ASPHALT, as there are imitations which are of but little value.

The Bituminous Sandstones of California have been extensively used for paving streets in Western cities. They are prepared for use as paving-materials by crushing to powder. With this powder a considerable proportion of sand or gravel is generally mixed and the mixture heated until it becomes plastic; it is then spread over the roadways and compressed by rolling.

MINERAL WOOL

Sources of Mineral Wool. There are at least two kinds of mineral wool made in this country. The more common quality is made by mixing certain kinds of stone with the MOLTEN SLAG from blast-furnaces and converting the whole mass into a fibrous state. The best slag for the purpose is that which is free from iron. The appearance of the finished product is much that like of wool, being soft and fibrous, but in no other respect are the materials alike. Mineral wool made from slag appears in a variety of colors, principally white, but often yellow or gray, and occasionally quite dark. The color, however, is said to be no indication of the quality, as all of the peculiar properties of the material are present in equal proportions in any of the shades. The other kind of mineral wool is known as ROCK-WOOL, and is made from granite rock raised to 3 000° F. It is claimed that as it is absolutely free from sulphur; it is the only odorless wool manufactured. It has been approved by the United States War Department. It has the same general appearance as that made from slag, and is white in color.

Nature of Mineral Wool. Both of these materials consist of a mass of very fine, pliant, but inelastic, vitreous fibers interlacing in every direction and forming an innumerable number of minute air-cells. Its great value in the insulation and protection of buildings lies in the number of air-cells which it contains, its consequent non-conduction of heat, and its fire-resisting qualities. In wool made from common slag, 92% of the volume consists of air held in minute cells, while in the best grade the proportion of air reaches as high as 96%. This confined air makes it one of the best, if not the best, of the non-conductors of heat. Aside from these qualities it is very durable and contains nothing that can decay or become musty. Being itself incombustible it greatly retards the burning of wooden floors or partitions if their inner spaces are filled with it.

Uses of Mineral Wool. The greatest value of this material is as an insulator of heat, but it is also a valuable non-conductor of sound. It is the general opinion, however, that it can be considered only as a MUFFLER of the sound-waves, for there seems to be no practical way in which it can be used so as to separate entirely the floor and ceiling. It would be crushed by laying floor-cleats upon it. As a muffler or filling between the beams, however, there is probably nothing that is superior.

Manner of Applying Mineral Wool. Mineral wool, when used alone as floor-deadening, may be laid on boards cut in between the joists, or on top of sheathing-lath when that material is used. The wool should be at least 2 in thick. Again, mineral wool is particularly desirable for filling the spaces between the studs of outside walls and partitions and between the rafters of roofs. It may be used to great advantage, also, in partitions around bath-rooms or water-closets, and around water-pipes when placed in partitions. In outside walls and attic roofs, as a protection from the heat of summer or the cold of winter, it is of the greatest value. By lathing the under side of the rafters with sheathing-lath, and spreading on top a layer of 2 or 3 in of mineral or rock-wool, the comfort of the room is greatly increased. Flat roofs over inhabited rooms may be covered with rough boards and 1¾-in cleats nailed on top, the spaces filled with wool, and the roof-sheathing then nailed to the cleats. This not only greatly increases the comfort of the rooms, but greatly retards the progress of fire from the outside. When insulating against heat, nails driven through the insulating material do no harm. When using mineral wool in floors it should be packed in very closely, but not jammed so as to break the fibers, which are naturally very brittle. In partitions it is packed between the studs and laths, so as to completely fill the spaces, the wool being put in after the lathing has reached a height of 2 or 3 ft. More laths are then put on, the spaces filled, and so on to the top. The wool should not be dropped from any considerable height, as the breaking up of the fibers destroys the insulating qualities of the material. In fact the tendency of mineral wool to settle and consolidate, if improperly or too loosely packed, is the only draw-back, except cost, to its use for insulation. The wool behind the lathing will not prevent the plaster from keying.

ESTIMATING THE COST OF BUILDINGS *

Cost of Buildings per Cubic Foot. The method of CUBIC-FOOT VALUES has been used more than any other in estimating the cost of any proposed building, before the plans and specifications are sufficiently complete for taking off the actual quantities. "Comparison of UNIT COSTS is the only scientific criterion by which to judge the economic merit of a structure, a machine or a method of doing work." † Two buildings in the same city, or district, built in the same style and for the same purpose, of the same materials, and on the same scale of wages and prices of materials, should cost the same, or very nearly the same, per cubic foot, although one building may be somewhat larger than the other and of different shape. It therefore follows that if we know the COST PER CUBIC FOOT of different classes of buildings, in different localities, we can approximate quite closely the cost of any proposed building by multiplying its cubic contents in feet by the known cost per cubic foot of a similar building already built in that locality.

Size of Building Proportioned to Cost per Cubic Foot. If the cost of a proposed building must be kept absolutely within a certain sum, the size of the building should be proportioned so that the CUBIC CONTENTS shall not exceed the quotient obtained by dividing the amount appropriated by the AVERAGE COST PER CUBIC FOOT of similar buildings. Even then it may be found, when the bids are opened, that they exceed the appropriation; but the excess is often a relatively small percentage of the total cost and the necessary reductions can be made without altering the main features of the building.

Methods of Computation. In estimating the cost by the METHOD OF CUBIC CONTENTS, it is of course necessary that the contents be computed on the same basis, in both the proposed building and the one already built. The cubic contents are generally computed from the basement or cellar-floor, to the average height of a flat roof, or, if there is a pitched roof, the finished portion of the attic is included, or that part which might be finished, mere air-spaces and open porches not being included. Vaults and areas under sidewalks, etc., are generally included as part of the basement. All measurements are to the outside of the walls and foundations. The estimated cost may or may not include the fees of the architect and other experts.

Other Methods of Estimating the Cost of Buildings. The cost of buildings, such as hospitals, theaters, schools, churches, barracks, dormitories, etc., is sometimes estimated by the COST PER BED, SITTING, INMATE, etc. Estimates are also based upon the COST PER SQUARE FOOT of GROUND OCCUPIED or of all the FLOOR-SPACE, in certain types of buildings.

* The editor is indebted to E. S. Hand and others for valuable data relating to this subject. Readers are referred to the Handbook of Cost Data for Contractors and Engineers, by H. P. Gillette, The New Building Estimator, by William Arthur, and The Building Estimator's Reference Book, by F. R. Walker. Many values given are pre-war values and may be used for relative costs.

† H. P. Gillette, in the preface to his Handbook of Cost Data for Contractors and Engineers.

Data * on Cubic-Foot Values as a Basis for Preliminary Estimates of Building Costs

Notes on Modifying Conditions. Buildings of a given TYPE, such as office-buildings and school-buildings, when similar in construction and finish and built under similar market-conditions as to cost of labor and materials, are found to be nearly identical in CUBIC-FOOT COSTS. The buildings of any such type do not differ widely in bulk, and this is always very considerable when compared with such structures as dwellings and small business buildings. This seems only another way of saying that similar causes produce similar effects, but it goes a step farther by indicating that the results here are virtually identical; so nearly so, that the AVERAGE CUBIC-FOOT COST of a certain kind of building can be relied on to produce an estimate within from 3 to 5% of the actual cost of new work of the same kind and under the same conditions. Other types of large structures, such as public buildings, hotels, churches and theaters, are less subject to standardization because more variable in equipment and finish. This is true also of dwellings, shops and other small structures whose lesser bulk, moreover, renders even less possible a close prediction as to their cost. These uncertainties do not, however, warrant the rejection of the CUBIC-FOOT-COST METHOD for preliminary estimating. They do indicate that it is less closely approximate for some types than for others. But the degree of uncertainty on even the most variable types may be minimized and should be reduced to perhaps 10% under a careful system of cost-computation. Such system should cover a considerable number of examples, taking account of all factors of material influence upon cost in each type, and must follow a consistently uniform method of determining cubic-foot values.

The Factors Which Influence Cost include the following:

(1) Prevailing market prices of labor and materials.

(2) Type of construction employed, depth and kind of foundations and existence of special features such as towers or domes.

(3) Finish: external facing and ornamentation; internal surfacing and decoration.

(4) Equipment: (*a*) number and complexity of heating, lighting, ventilating, sanitary, elevator and other systems; (*b*) extent to which apparatus or equipment, such as laboratory-devices, opera-chairs, bank-counters, etc., is provided for direct use of occupants of building.

(5) Fees of architect and other experts.

(6) Locality: Costs of structures of a given type will vary with the locality because of differing standards of practice and building laws, availability of building materials, labor, etc.

(7) Other items, developing in the experience of the architect.

The Method of Determining Cubage may either simply recognize the GEOMETRICAL VOLUME of the building or, better, may employ a COEFFICIENT OF VALUE for any part whose cost varies materially from the average. The latter method may be preferred as allowing a closer calculation of variations

* The data given in paragraphs: Notes on Modifying Conditions, The Factors Which Influence Cost, The Method of Determining Cubage, and Cubic-Foot Costs are quoted, by permission, from notes relating to this subject, compiled by Dr. Warren P. Laird from the study of a large number of public and private buildings erected in widely separated districts of the United States. For these buildings Dr. Laird acted as the professional adviser for the selection of the architect, and in all cases the estimate of the cost of the buildings was based strictly upon a total number of cubic feet and a fixed unit cost per cubic foot.

from known examples. For instance, an unfinished cellar or other story or a small light-court would cost less per cubic foot than the remainder of the building, while a tower or dome of finished basement containing, also, an expensive mechanical plant, would cost more. Foundations sometimes cost so much that they require figuring to their full depths as though the finished building were carried down to that level.

Cubic-Foot Costs. Subject to the foregoing considerations, the following data on fire-proof buildings may be taken as approximately safe, depending upon the location of the project.

Construction: steel and terra-cotta, stone and brick facings, complete equipment and superior grade of interior finish:

Type of Building	Cents per cubic foot
Office-buildings	65 to 85
Public buildings	80 to 100
School-buildings	45 to 60

Cost-Data of Buildings

Cost of Some Notable Buildings in New York City. Some of the more prominent buildings in the Borough of Manhattan, City of New York, are included in the following table. For all these structures the costs per cubic foot are given. By reason of its height the Woolworth Building may be considered the most notable of the list. The cubic contents total nearly 12 000 000 cu ft. Its foundations are carried to rock, which is about 120 feet below the street-surface. The approximate weight of its steel frame is 23 000 tons.

The Grand Central Station, as a complete terminal, is a very complex structure, but there is a distinct part which contains the passenger-concourse and the waiting-rooms, restaurant and other parts that are considered necessary to care for the traffic. The cubic contents of this part total about 14 000 000 cu ft. Other parts of the building are not considered in the present reference. Some interesting facts as to the main station, only, are:

Cost, about	$8 000 000
Ground-area above street-level, square feet	266 000
Additonal station-facilities under street, square feet,	80 000
Floor-area devoted to station-purposes, square feet	1 188 000
Cubic contents, about, cubic feet	32 857 800
Steel used in construction, tons	35 767
Weight of largest girder used, tons	30

Cost of Various College Buildings. The following table giving the cost per cubic foot of various college buildings is taken from College Architecture in America by Charles Z. Klauder and Herbert C. Wise. In presenting these figures the authors call attention to the fact that data were received from many sources and that, owing to various methods of computing cubage as well as variations in the items considered in computing the actual cost of the buildings, the figures are approximate.

Administration and academic buildings	58 ct
Libraries and museums	65 ct
Chapels and auditoriums	47 ct
Science (laboratory) buildings	75 ct
Engineering and shop buildings	45 ct
Gymnasiums	32 ct
Indoor stadia	23 ct

Cost-Data of Some Notable Pre-War Buildings in New York City *

Name of building	Description	Heights, ft	Ground-areas, sq ft	Total floor-areas, sq ft	Cost	Cubic contents, cu ft	Costs per cubic foot cents
Altman Building [1]	8-story department-store.	152	54 850	495 000	.	.	33

† "Tare" represents plan area occupied by corridors, stairways, lavatories (toilet-rooms), porters', housemaids' and other hall closets, partitions and exterior walls.

Dwight James Baum was the architect for the following buildings.

Building	Location	Date	Stories	Remarks	Cost per cu ft, ct
West Side Y. M. C. A Building	New York City	1929	14	Cost per cubic foot includes certain complicated equipment common to buildings of this type	68
Ridgewood Bank.	Ridgewood, N J	1930	2 and base-	Cost per cubic foot includes special equipment such as is usually required in a suburban bank, including steel vaults and a complicated system of intercommunication	90
Residence...	Bay Shore, L. I.	1929	$2\frac{1}{2}$	Mr. Baum states that 73 ct per cu ft is the average cost of residences constructed in the neighborhood of New York City for his office.	73

Horace W. Castor was the architect for the following buildings:

Building	Location	Date	Stories	Cu ft	Remarks	Cost per cu ft, ct
Hospital . .	Philadelphia, Pa	1927–28	6 and basement	934 900	Steel frame, concrete arches, brick spandrel walls, tile and terrazzo floors, marble wainscot Building contains private rooms and baths, X-ray department, operating-rooms, laboratories, offices and kitchens	$69\frac{1}{2}$ (With furniture, draperies and lighting fixtures, $71\frac{1}{2}$)
Home for Old Folks	Philadelphia, Pa	1926	6 and basement	894 180	Reinforced-concrete, brick spandrel walls, terrazzo floors Building contains private rooms, infirmary, chapel, dining-hall, kitchens, heating plant, social hall, sun-rooms, recreation-rooms, laundry	$65\frac{1}{2}$
Masonic Building (Consistory)	Philadelphia, Pa	1926–27		2 736 210	Steel frame, concrete arches, limestone facing with terra-cotta trim, marble and terrazzo floors, marble wainscoting. Building contains auditorium (seating 2 100) library, banquet rooms, kitchens, stage and equipment, offices, assembly-rooms, lounges, heating and ventilating equipment.	$46\frac{1}{2}$ (With stage equipment, chairs in auditorium, organ, lighting fixtures, kitchen equipment, furniture and furnishings, $52\frac{1}{2}$)

Rankin and Kellogg were the architects for the following buildings:

Building	Location	Date	Stories	Cu ft	Remarks	Cost per cu ft
Elverson Building (Home of "Philadelphia Inquirer")	Philadelphia, Pa..	1925	13 tower additional	7 427 000	Fire-proof, terra-cotta exterior Building built over railroad.	46 ct, including tower, clock, and chimes.
Provident Trust Co. Building	Philadelphia, Pa ..	1928	12 and basement	1 850 000	Fire-proof, brick and marble exterior; interior, first-class office-building finish.	$ 876, including vaults
Philadelphia Wholesale Drug Co.	Philadelphia, Pa..	1928	.	2 250 000	Fire-proof, brick and artificial stone exterior Considerable portion of interior unplastered and without partitions	$ 261
Montgomery County Court House Annex.	Norriston, Pa...	1930	.	1 140 000	Fire-proof, Vermont light blue marble exterior Interior, first-class office-building finish	$.715
Administration Building, U. S Department of Agriculture	Washington, D C	1930	. .	2 655 000	Fire-proof. White Georgia marble exterior Interior, first-class office-building finish.	$.626
Camden Safe Deposit and Trust Co. Building	Camden, N. J......	1930	3	854 000	Fire-proof. Deer Island granite exterior Entire building used for trust company purposes and finished appropriately.	$1 17, including vaults

Thomas, Martin and Kirkpatrick were the architects for the following buildings:

Building	Location	Date	Stories	Remarks	Cost per cu ft, ct
Y. M. C. A. Building	Easton, Pa	1920	4	Concrete	53
Y. M. C. A. Building	Williamsport, Pa	1923	4	Concrete	40

Paul P. Cret was the architect for the following buildings:

Building	Location	Date	Stories	Cu ft	Remarks	Cost per cu ft
Barnes Foundation	Merion, Pa	1923	2 and basement	398 850	Art gallery, fire-proof, French limestone exterior	$ 876
John Herron Art Institute Art School	Indianapolis, Ind	1928	2 and basement	246 800	Brick, limestone trim, concrete floors	.50
Memorial to Quentin Roosevelt	Chamery, France	1920	.	1 700	Fountain, French limestone	1 63
Residence	Haverford, Pa	1926	2 and basement	103 009	Local stone, fine cabinet work, wood framing.	873
Gatehouse	Villa Nova, Pa.	1928	2 and basement	21 886	Local stone, wood framing	.634

John Russell Pope was the architect for the following buildings: *

Building	Location	Date	Stories	Remarks	Cost per cu ft
Marcus Ward Home.	Maplewood, N. J.	1927–29	2	A group of three buildings Neshaminy Pennsylvania Quarry stone, slate roofs and metal windows. 72 bed-rooms, each with fire-place. Fireproof.	$.98
The D. A. R. Constitution Hall.	Washington, D C.	1928–29		Auditorium seats 4000. The building includes a Library group. Exterior is of limestone, interior is of plaster Span of auditorium, 180 ft	$.58
First Presbyterian Church of New Rochelle.	New Rochelle, N.Y.	1928–29		Local rubble stone and wood trim. Group consists of church, seating 500, tower and Sunday School.	$ 60
Hendricks Chapel, Syracuse University.	Syracuse, N Y	1929–30		Brick and limestone, lead-coated copper dome Seats 1450. Interior, ornamental plaster and wood.	$ 67
Syracuse Memorial Hospital.	Syracuse, N Y.	1927–29		Group consists of Administration Building, Patients' Building and Nurses' Home Brick and limestone, 300 patients.	$ 82
Club House for the Junior League of the City of New York.	New York City, Borough of Manhattan.	1928–29	7	Brick and limestone First, second and third floors for entertaining; fourth floor, bedrooms and offices; fifth floor, nursery for Social Service; sixth and seventh floors, swimming-pool and two hand-ball courts.	$ 96

* The data presented in this table were prepared by the Office of John Russell Pope. The cubic-foot cost has been computed including all equipment of an attached nature necessary to the complete operation of the building, as well as kitchen tables, bread- and meat-cutting machines, clothes-assorting tables, etc The figures given are exclusive of Architect's and Engineer's fees and removable furniture, rugs and draperies.

Detroit Institute of Arts, Detroit, Mich. Architects· Paul P. Cret and Zautzinger, Borie and Medary. This building, erected in 1923–1927, contains an art gallery and large concert hall. It is of fire-proof construction, 2 stories and basement, with a marble exterior, contains 5 661 688 cu ft; the approximate cost per cu ft was 80 ct.

Rodin Museum, Philadelphia, Pa. Architects: Paul P. Cret and Jacques Greber. Erected in 1929, this building is of fire-proof construction having an Indiana limestone exterior, and contains an art gallery. It contains one story

and basement, has a cubage of 248 000 cu ft and cost approximately 80 ct per cu ft.

Hartford County Building, Hartford, Conn. Architects: Paul P. Cret and Smith and Bassette. This building, erected in 1926–1928, contains 3 stories and basement. It is of fire-proof construction, having an Indiana limestone exterior. The cubage is 1 461 051 cu ft and cost approximately $1.04 per cu ft.

Apartments, Bryn Mawr, Pa. Architect: John F. Harbeson. This apartment-building was built in 1923; it contains 3 stories and basement. It is of brick and frame construction, has a cubage of 573 400 cu ft and cost approximately 48 ct per cu ft.

Residence at Chestnut Hill, Philadelphia, Pa. Architect: Robert R. McGoodwin. This building, erected in 1929, was built of local stone for exterior walls with cast-stone trim, tile roof, hardwood floors, tile bathrooms and vapor heat. All framing was of wood. The height was 2½ stories. The approximate cost was 55 ct per cu ft.

Public-School Buildings. Davis and Dunlap were the architects for the following three school buildings:

Junior High School Building

Location: Wyncote, Penna
Date of construction: 1928.

Contents:	Auditorium;	Shops;
	Gymnasium;	Library;
	Cafeteria;	Rest-rooms;
		Class-rooms.

Construction: Fire-proof; stone and concrete.
Pupil capacity: 745.
Total usable floor-space: 24 745 sq ft
Total cost of construction (including architects). $283 699
Cost of equipment, approximately: 20 000

Cost per pupil: $380	Cost per sq ft usable space. $11 42	Number of sq ft per pupil: 33
Cost per pupil with equipment: $407	Cost per sq ft usable space, with equipment $12 27	

Note. Square foot usable floor-space includes: Class-rooms, auditorium, gymnasium, showers and lockers, offices, teachers', library, toilets and special rooms. (No corridors, walls, stairs, boiler-room, janitor, storage, cafeteria)

Cost per cu ft: 28½ ct (without architects' commission or equipment).

Junior High School Building

Location: Camden, N. J.
Date of construction: 1929.

Contents: Auditorium; Shops;
Gymnasium; Library;
Cafeteria; Class-rooms.

Construction: Fire-proof; brick and concrete.
Pupil capacity: 1 400.
Total usable floor-space: 53 692 sq ft.
Total cost of construction (including architects): $656 816
Cost of equipment, approximately: $40 000

Cost per pupil:	Cost per sq ft usable space:	Number of sq ft per pupil:
$462	$10	39.80
Cost per pupil with equipment:	**Cost per sq ft usable space, with equipment:**	
$497	$12	

NOTE. Square foot usable floor-space includes Class-rooms, auditorium, gymnasium, showers and lockers, offices, teachers', library, toilets and special rooms. (No corridors, walls, stairs, boiler-room, janitor, storage, cafeteria)

Cost per cu ft: 30 ct.

Federal Buildings.* In presenting data for the following seven Federal Buildings it should be noted that the cubic-foot rates on the projects cited are based upon the lowest bid submitted. Competition on public-building construction results in a large number of bidders and the range in the proposals submitted results in a difference varying from 50% to over 100% over the lowest bidder. It is obvious that any unit rate per cubic foot of volume determined on the basis of the low bid is not a true index to the cost of a particular building.

Worcester, Mass. Contract awarded June, 1930.

A five-story and basement building of fire-proof construction; the exterior walls faced with granite, flat roof, steel sash, main entrance lobby marble wainscot, ornamented plaster ceiling; the first and second floors devoted to postal service and three upper floors of typical office finish.

Ground area	17 700 sq ft
Cubical contents	1 225 000 cu ft
Rate per cu ft	60 ct

White Plains, New York. Contract awarded August, 1930.

Basement, one and part two-story fire-proof building, brick faced with stone trimming, flat roof; interior public lobby having marble wainscot and ornamented plaster ceiling; second floor typical office finish.

Ground area	12 600 sq ft
Cubical contents	466 000 cu ft
Rate per cu ft	41 ct

Lima, Ohio. Contract awarded January, 1930.

One-story and basement fire-proof building; exterior facing of limestone, copper-covered pitched roof, steel sash; main entrance lobby marble wainscot, ornamented plaster ceiling.

Ground area	20 000 sq ft
Cubical contents	712 000 cu ft
Rate per cu ft	41 ct

Flint, Mich. Contract awarded July. 1930.

Basement, one and part two-story building of fire-proof construction, limestone face, slate-covered pitched roof over two-story portion, flat roof elsewhere, steel sash; main lobby marble wainscot, ornamented plaster ceiling.

Ground area	24 000 sq ft
Cubical contents	1 027 000 cu ft
Rate per cu ft	35 ct

San Bernardino, Calif. Contract awarded June, 1930.

Two-story and basement building of fire-proof construction; exterior of brick with stucco facing and architectural terra-cotta trimming, tile roof; main lobby marble wainscot, ornamental plaster ceiling.

Ground area	15 000 sq ft
Cubical contents	598 000 cu ft
Rate per cu ft	39 ct

Asheville, N. C. Contract award July, 1929.

* Data for the seven Federal Buildings here listed have been presented by the Office of Supervising Architect, James A. Wetmore, Acting Supervising Architect.

Three-story and basement, fire-proof construction, granite-faced to first-floor line, limestone-faced elsewhere except rear and courts which are of brick, copper-covered pitched roof, steel sash; main lobby wainscot, ornamented plaster ceiling.

Ground area	24 200 sq ft
Cubical contents	1 380 253 cu ft
Rate per cu ft	45 ct

Springfield, Ill. Contract awarded December, 1929.

Three-story and basement building, fire-proof construction, limestone facing, except rear; copper-covered pitched roof, main lobby limestone wainscot 4 ft high, plaster walls, ornamented ceiling.

Ground area	29 700 sq ft
Cubical contents	1 638 000 cu ft
Rate per cu ft	43 ct

Of new federal buildings in the District of Columbia, those of the Internal Revenue and the Department of Commerce are the only two upon which the office has any definite data. The building of Internal Revenue has a ground area of approximately 150 000 sq ft and 16 100 000 cu ft volume. It is a seven-story building, limestone faced, with Tennessee marble columns, and tile roof. When completed it will have cost approximately 50 ct per cu ft.

The Commerce Building has a ground area of approximately 176 000 sq ft and a content of approximately 27 160 000 cu ft, entirely limestone-faced, tile roof, and will cost, when completed, approximately 60 ct per cu ft.

Percentages of Cost of Items of Construction in Fire-Proof Buildings

The tables * on the following pages show the DIVISION OF THE COSTS of fire-proof buildings among the different materials and parts of the construction, the data having been furnished the compiler by architects and builders in the cities mentioned in the tables. Each column of values in the tables gives the data for an individual building, except the values for New York City, in the second, third and fifth columns, which show the averages for a large number of buildings. The tables on the first four pages include only buildings approximating closely the standard specifications of the National Board of Fire Underwriters. The tables show that the foundations and steel frames, the only parts little damaged in conflagrations, represent, approximately, only 25% of the entire sound value of a building. For example, in the tables on the first four pages, the average cost of all the foundations is 8%, while the average cost of the steel frames is 17.88%.

* The six following tables were compiled by F. J. T. Stewart, Continental Insurance Company. All are reproduced, by permission, from J. K. Freitag's Fire Prevention and Fire Protection.

Cost of Elements of Five Buildings

The buildings numbered 1 to 5 in the following table were constructed in New York in 1926. Decimals are proportions of the total cost (labor and materials) of the building:

Building No. 1. Office and Exchange, steel frame (fire-proof), limestone front and trim, 101 by 116; 23 stories and basement and two penthouses, 261 000 sq ft, 3 738 000 cu ft. (Geo. A. Fuller, New York)

Building No. 2. Office and Bank, steel frame (fire-proof), limestone front and trim, 65.5 by 145.25; 12 stories and basement, 125 887 sq ft, 1 569 512 cu ft. (Geo. A. Fuller, New York)

Building No. 3. Hotel, reinforced concrete (fire-proof), face-brick front, terra-cotta trim, 172 by 200; 10 stories and penthouse, 234 631 sq ft, 3 017 015 cu ft. (Geo. A. Fuller, New York)

Building No. 4. Factory, reinforced concrete, $461 711. Brooklyn. (Barney-Ahlers Construction Corporation.)

Building No. 5. Factory, reinforced concrete; $213 666; Long Island City, N. Y. (Barney-Ahlers Construction Corporation.)

Cost of Elements on Five Buildings*

Main operations	Included in main operations	Number of building 1	2	3	4	5
General conditions	Permits, bond, insurance, association fee, damage, heat, plant	0523	.03	.04	.094	.0724
Masonry	Wrecking, excavation, blasting, shoring, waterproofing, pumping, brick stack	.0924	.1650	.1330	.07	.14

Cost of Buildings per Square Foot

One-Story Buildings of Large Area, such as exposition-buildings, etc., may be estimated almost as accurately by the square foot of ground covered as by the cubic foot of building, as there are few or no interior partitions, and usually no plastering or interior finish. The cost of buildings for the Chicago World's Fair (1893), the St. Louis Exposition (1904), the San Francisco Exposition (1915) and the Philadelphia Sesqui-Centennial Exposition (1926) are given here for purposes of comparison.

Exposition-Buildings. The cost * of the **World's Fair buildings (Chicago, 1893)** per square foot of ground covered, including sculpture and decoration, was as follows:

Manufactures and Liberal Arts Building	$1 39
Transportation Building	1 08
Electricity Building	1 69
Machinery Hall	2 12
Agricultural Building	1 44
Administration Building	9 18
Horticultural Building	1 41
Mines and Mining Building	1 04
Fisheries Building	2.35
Forestry Building	0.75

Cost of Structures for the St. Louis Exposition (1904). The following figures were issued by Isaac S. Taylor, at that time Director of Works, of the World's Fair, showing the area and cost of the principal exhibition-buildings. The total area of twenty-two buildings was 123.51 acres, and the total cost $6 939 992.26. The cost was for the bare buildings, and did not include sculptural or other decorations, or the architects' compensation.

Building	Dimensions, ft	Area, acres	Total cost	Cost, sq ft
Art	161×346	1 42	$967 833 90	$5 45
Two Art Pavilions, each	144×423	3 14		
Art Building Annex	106×150	0 41	39 388 99	2.48
Government Building	200×736	3 86	328 980 00	2.23
Government Fisheries	136×136	0 42	45 000 00	2.43
Mines and Metallurgy	525×750	9.08	488 848.50	1.24
Liberal Arts	525×750	8 80	471 820 95	1.20
Education and Social Economy	525×758	7.70	323 950.75	0.81
Manufactures	525×1 200	13 47	711 510.00	1.13
Electricity	525×758	6 67	408 531.57	1.03

Machinery	525×1 000	9.48	509 110.50	0 97
Steam, Gas and Fuel	301×326⅔	2 25	135 480.00	1 38
Transportation	525×1 300	15 70	674 853.42	0.99
Horticulture	374×782	5 42	225 342 27	0.77
Agriculture	500×1 600	18 62	520 491.07	0.58
Forestry, Fish and Game	300×600	4.07	168 883.38	0.94
Festival Hall	195 in diameter, exclusive of annex	1.09	215 899.00	. .

* Given by E. C. Chankland, chief engineer.

The Panama-Pacific International Exposition at San Francisco (1915). The following table was taken from the Official History of the International Celebration held at San Francisco, by Frank Morton Todd. The eleven buildings, exclusive of the California Building and the Motor Transportation Building, which were exceptional, covered over 64 acres, including grading, sewers, conduit systems, foundations and everything complete.

Ground Areas and Construction Costs

Building	Area, sq ft	Cost	Cost per sq ft
Fine Arts and Annex*	148 558	$631,929.92	$4.25
Education	205 127	300 183.04	1.46
Food Products	236 752	326 594.69	1 38
Liberal Arts	251 269	325 447.90	1 29
Agriculture	328 419	386 351.48	1 17
Manufactures	234 481	317 436 35	1.35
Transportation	314 345	451 560 70	1 43
Varied Industries	219 453	296 554 07	1 35
Mines and Metallurgy	252 613	338 549.25	1.34
Machinery	369 562	655 336.35	1 77
Horticulture	234 486	352 615.90	1.50
	2 795 065	$4 382 559.65	$1.56 (average)

* Annex had two floors.

Sesqui-Centennial International Exposition at Philadelphia (1926). The table is taken from data prepared by the late John Molitor, City Architect and Supervising Architect of the Exposition, and also from his successor as City Architect, Wm. S. Covell.

Ground Areas and Construction Costs* of Principal Buildings

Building	Ground area, sq ft	Extreme dimensions	Cost	Cost per sq ft	Cost per cu ft
Liberal Arts	338 596	970×392	$976 649 88	$2.88	$.084
Agriculture and Food Products	367 592	970×460	957 427 76	2 60	.076
Auditorium	111 273	445×274	471 314 00	4.23	.10
Transportation	316 124	880×400	938 196 00	2 96	.06
Educational	104 936	524×208	441 389 00	4 20	.14
Fine Arts	68 000	496×258	325 881.86	4 79	.22
Administration (two stories)	9 198	200× 73	70 541 66	7.66	.26

* No heating was installed in any building except the Administration Building.

Depreciation of Buildings

The Average Annual Physical Depreciation of Buildings is given in the following table:*

Building	Annual physical depreciation, per cent
Academies with dormitories	3–4
without dormitories	3½
Agricultural, brick	1–3
frame	2–4
Amusement buildings	1
Apartment-houses, fire-proof	1½
non-fire-proof	3 (5 yr) 2½ (5 yr) 2 for remainder of life (Zangerle)
Asylum, brick or stone	2½–3
frame	3½–4
Auditorium	1
Bakery	3
Bank	2–2½
Barns, brick	3
frame	4
Bath-houses	1
Brick residences, occupied by owner	1–1¼
occupied by tenant	1¼–1½
Frame residences, occupied by owner	2–2½
occupied by tenant	2½–3
Churches, brick	1–2
frame	3–4
Clubhouses	1
Cotton mills	2–3½
Court-houses	2–5
Exhibition halls	1
Factories	
all frame	5
box and door	5
candle, brick	3
frame	5
canning, brick	2
frame	4
cheese, brick	2½
frame	3½
hat	1½–2½
engineering	5–10
starch, brick	3
frame	5
Filling stations, oil, ordinary wood or corrugated steel	20
brick and concrete	10
Fire-proof, modern	2–4
Flour-mill, brick or stone	2–2½
frame	3–3½
Garages	4
Gas-plant	1⅓–3
Glass-works, brick or frame	4
concrete	2½
Grain-elevators	2½–4½
Hardware-works, brick	3½
frame	4
Horticultural	2
Hotel, brick and stone	2½–3½
fire-proof	1½
frame	3½–4½
non-fire-resisting	3 (5 yr) 2½ (5 yr) 2 for remainder of life
Ice-house, brick	3
frame	4–10
Industrial, fire-resisting	1½ (10 yr) 1 for remainder of life
Institutions	2–2¼
Kilns, brick, tile, or concrete	10
frame	25
Lofts and factories	2⅔–3
Machine-tool industry, brick	3
frame	5
Mills, paint	7½
paper	2½–3½
planing	5
rolling, brick	2½
frame	4
saw	7–10
woolen	2–3½
Museums	1
Nail-mill, brick	2½
frame	4

railroad	2⅔–3	glass, brick	3–4
1st and 2d class	1⅓–2	frame	4–4½
Stables, brick	3–5	hardware, brick	3½
frame	4–10	frame	4
Starch plant, brick	3	nail, brick	2½
frame	5	frame	4
Stations and waiting-rooms, railroads	2–3	salt, frame	4

THE QUANTITY SYSTEM

Explanation of the System. The QUANTITY SYSTEM is not, as some persons have supposed, merely the taking off of a list of items by one person, probably with uncertain accuracy, for some other person's use. It means the careful measurement by a disinterested expert specially trained in this kind of work, that is, a QUANTITY SURVEYOR. This specialist proceeds in a manner quite different from that of the average contractor. He follows a certain recognized order and system in taking off quantities, abstracting and billing, with a view to eliminating errors. He uses certain uniform standards of measurements and expressions well understood by bidders. His checking and rechecking methods to ensure accuracy must be studied to be appreciated by those to whom the quantity system is unknown. A record is kept of every item, however small, having a money-value. These items are classified and arranged, each under its proper trade or department, in methodical order. Guess-work methods are unknown to the quantity surveyor, while his accuracy and attention to even small details is worthy of comment. Every bidder figures from a copy of the surveyor's quantities furnished to each one, with

(if desired) the plans and specifications. The surveyor who does this work is a professional man similar to the engineer or the architect. He should, in fact, have, and he usually has had, experience in these professions, and in addition, at practical experience acquired in the field in actual contact with and superintendence of construction-work.

Method of Procedure. Such a surveyor, in taking off quantities from an architect's or engineer's drawings, readily detects any discrepancies due to hasty preparation or other cause. The attention of the architect or engineer is called to such matters by the quantity surveyor, as he goes on with his work. Detected in this way, all uncertainties are at once corrected and adjusted, so that by the time the drawings and specifications reach contractors, everything has been made plain and accurate and the possibility of error in quantities can therefore be disregarded. The resulting document, the BILL OF QUANTITIES, is then either printed or otherwise reproduced, and a facsimile copy supplied free of cost to each bidder who inserts his unit price opposite each item and in an hour or two foots up the money-cost in dollars and cents. This is really all that a contractor should be expected to do (for nothing). The BILL OF QUANTITIES contains everything the contractor is called upon to perform or furnish, in order to complete his contract. In short, the bid becomes a proposal to do a certain FIXED QUANTITY of work, no more and no less. This then, briefly, is the main underlying principle of the QUANTITY SYSTEM: a definite quantity of work for a definite price, and the elimination of every condition which now compels bidders to take chances.

Advantages Claimed for the Quantity System. The following are the advantages claimed for the system:

(1) An immense saving of time and money now wasted by bidders; all doing the same thing, going over the same ground, and each arriving at a different result.

(2) Safer bids, as the work to be performed is clearly written out in the bill of quantities, which can be the essence of the contract.

(3) No expense to the bidder; the owner pays for the quantities knowingly. The owners pay now, but this fact is not brought to their attention, and it does not occur to them. The percentage added to a bidder's net cost is not all profit, a certain portion being absorbed in overhead charges, including cost of estimating, which, of course, is ultimately borne by owners.

(4) Saving of disputes arising from ambiguities, oversights, and even errors, all causing extra claims more or less just, but usually vexatious, and sometimes embarrassing.

(5) Better opportunities for the competent bidder, as the bidders all work up and price from the same basis.

(6) Better work and greater harmony If no part of the work is omitted there is less reason to skin the work, a proceeding which produces friction, or worse.

(7) Misunderstandings are reduced. The bill of quantities states clearly what is intended, and is a sort of clearing-house for the drawings and specifications.

(8) Neither party can obtain an advantage over the other on quantity or description of work.

(9) No disputes with subbidders, it being clearly stated what each trade is to furnish.

(10) Contractors have no figuring of quantities to do and can therefore devote more time to buildings in hand and save profits now lost for want of their personal supervision.

(11) Fewer inferior contractors as lowest bidders.

(12) Fewer extras, which are usually a trouble to all concerned.

(13) The architect or engineer has the assistance by collaboration of the professional quantity surveyor, who is available, also, for preliminary figures. This advance-information, now so often furnished by a prospective bidder, creates undesirable obligations.

(14) No change or reorganizing of architects' offices is entailed. Much detail-work now involved in receiving bids could be taken care of in the quantity surveyor's office.

(15) The drawings and specifications having been previously made as complete as possible, subsequent inconvenience to contractors and foremen on the job, and inquiries at the architects' offices for explanations become unnecessary. The BILL OF QUANTITIES gives detailed information which cannot be well given by drawings.

DIMENSIONS AND DATA USEFUL IN THE PREPARATION OF ARCHITECTS' DRAWINGS AND SPECIFICATIONS

Dimensions for Furniture. For the convenience of draughtsmen when designing furniture or providing space for a special article the following approximate dimensions are given:

Chairs and Seats. The average figures taken from a variety of good chairs are: Height of the seat above the floor, 18 in; depth of the seat, 19 in; the top of the back above the floor, 38 in. Usually the seat increases in depth as it decreases in height, while the back is higher and slopes more. Twenty inches inside is a comfortable depth for a seat of moderate size. Chair-arms are about 9 in above the seat. The slope of the back should not be more than one-fifth the depth of the seat. A LOUNGE is 6 ft long and about 30 in wide.

Tables vary in shape and size almost as much as chairs. Writing-tables and dining-tables are made 2 ft 5 in high, and the type of sideboard called a CARVING-TABLE is made 3 ft high to the principal shelf; but tables for general use are 2 ft 6 in high. DINING-TABLES are made from 3 ft 6 in to 4 ft wide and to extend from 12 ft to 16 ft by means of slides within the frame. This frame should not be so deep as to interfere with the knees of any one sitting at the table; that is, there must be about 2 ft clear space between it and the floor. The smallest size practicable for the KNEE-HOLES of desks and library-tables is 2 ft high by 1 ft 8 in wide, the width to be increased as much as possible.

Bedsteads are classed as SINGLE, THREE-QUARTERS, and DOUBLE. A single bed is from 3 to 4 ft wide inside; a three-quarter bed, from 4 ft to 4 ft 6 in; a double bed, 5 ft. Bedsteads are from 6 ft 6 in to 6 ft 8 in long inside. Footboards are from 2 ft 6 in to 3 ft 6 in and headboards from 5 ft to 6 ft 6 in high. Single beds for dormitories are often made only 2 ft 8 in wide.

Bureaus vary in shape and size to such an extent that it is almost impossible to say that any dimension is fixed. Convenient sizes are: body, 3 ft 5 in wide, 1 ft 6 in deep, and 2 ft 6 in high; or 4 ft wide, 1 ft 8 in deep and 3 ft high.

Chiffoniers are about 3 ft wide, 1 ft 8 in deep and 4 ft 4 in high.

Cheval-Glasses are made, if large, 6 ft 4 in high and 3 ft 2 in wide. If small, 5 ft high and 1 ft 8 in wide. If medium, 5 ft 6 in high and 2 ft wide.

Sideboards may be from 4 to 6 ft long and from 20 in to 2 ft 2 in deep.

Upright Pianos vary from 4 ft 10 in to 5 ft 6 in in length, from 4 to 4 ft. 9 in in height and are about 2 ft 4 in deep over all.

Miniature and Baby-Grand Pianos vary from 5 ft 10 in to 6 ft in length, and are about 4 ft 10 in in width.

Grand Pianos vary from 5½ ft to 6 ft 10 in in length, and are about 4 ft 10 in in width.

Concert-Grand Pianos are about 8 ft 10 in in length and 5 ft in width.

Billiard-Tables (Collender), 4 by 8 ft, 4 ft 2 in by 9 ft and 5 by 10 ft. Size of room required 13 by 17 ft, 14 by 18 ft and 15 by 20 ft, respectively.

Dimensions of Plumbing-Fixtures. Enameled-Iron Bath-Tubs. Standard sizes for roll-rim baths are: nominal lengths, 4 ft, 4½ ft, 5 ft, 5½ ft and 6 ft; width over all, from 30 to 34 in. Specially narrow tubs are made from 25 to 29 in wide. The actual length over rim is usually 1 or 2 in more than the nominal length, and 3 in will include an ordinary overflow-pipe.

Lavatories are made in various sizes, the average sizes varying from 20 in by 18 in to 30 in by 24 in.

Water-Closets have the following average dimensions. height to top of tank, 34 in to 39 in; length of tank, 23 in, wall to front, 24 in to 30 in. The smallest space permissible for water-closet compartments, where doors open out, is 2 ft 4 in by 3 ft 3 in. If the doors open in, the compartment should be 3 by 5 ft.

Closet-Ranges, used in schools and factories, are made 24, 27 and 30 in, center to center of partitions. For graded schools, 24 in is ample, and for factories, 27 in. The range usually occupies a space 28 in in depth, if set against a wall.

Urinal-Partitions should be from 24 to 27 in, center to center of partitions; depth of partitions, 20 or 22 in; of ends, 2 ft; of bottom slab, 2 ft; height of partitions, from 4 ft 6 in to 5 ft 6 in. Porcelain stall urinals have nominal widths of 18 and 24 in, and may be set with or without spaces between. Heights are usually about 40 in above the floor-level.

Kitchen-Sinks are made in a great variety of sizes, those most commonly used being 16 by 24 in, 18 by 30 in, 18 by 36 in, 20 by 30 in and 20 by 36 in. The depth inside, for the sizes given, is 6 in.

Cast-Iron Slop-Sinks, common sizes, are 16 by 16 in, 16 by 20 in, 18 by 22 in and 20 by 24 in; 12 in deep.

Copper Pantry-Sinks. Common sizes are 12 by 18 in, 14 by 20 in and 16 by 24 in; 6 in deep.

Laundry-Trays of slate or soapstone are commonly made 2 ft wide over all and 16 in deep. Lengths over all, two-part trays, 4 ft and 4 ft 6 in; three-part trays, 6 ft, 6 ft 6 in and 7 ft. Earthen and porcelain trays come separately, and are connected as required. The dimensions of each tray are 2 ft or 2 ft 7½ in in length, 2 ft 1½ in in width and 15 in in depth, inside. The length required for two 2-ft trays is 4 ft 1 in; for three trays, 6 ft 2 in; and for four trays, 8 ft 3 in.

Range-Boilers are 12 in diameter for 30-gal, 14 in for 40-gal, 16 in for 52-gal and 63-gal, 22 in for 100-gal and 120-gal boilers.

Passenger Automobile. Length from 11 to 19 ft; width, 6 ft; height, 5 ft 6 in to 6 ft 4 in. Turning diameters vary from 34 to 53 ft.

Dimensions of Locomotives and Cars. The dimensions of locomotives and freight-cars vary considerably, but the following will cover those in common use:

Locomotives. From 15 ft 4 in to 16 ft 3 in to top of stack from top of rail; extreme width of cab, 11 ft 6 in. Doors to admit locomotives should be from 12 to 13 ft wide and 18 ft high. Extreme width over cylinders, 10 ft 6 in. to 11 ft 9 in.

Automobile and Furniture-Cars are from 15 ft to 16 ft 2 in, from top of track to top of rake-staff; floor, 3 ft 6 in to 4 ft 2 in from track; extreme width, 10 ft to 11 ft.

Stock-Cars, from 13 ft 5 in to 14 ft 6 in, from top of track to top of brake-staff; floor, 3 ft 6 in to 4 ft 2 in from track; extreme width, 10 ft to 11 ft 2 in.

Refrigerator-Cars, 14 ft 6 in, from top of track to top of brake-staff; floor, 3 ft 6 in to 4 ft 2 in from track; extreme width, 10 ft.

Hopper-Cars, from 10 ft to 12 ft 6 in, from top of rail to top of brake-staff; extreme width, from 10 ft to 10 ft 6 in.

Gondola and Open-top Cars, from 7 ft to 13 ft from top of rail to top of brake-staff. Floor, 3 ft 2 in to 4 ft 6 in; extreme width, 10 ft to 11 ft 3 in.

Doors to admit box-cars should be 22 ft high, to permit a man to stand on top. Minimum width of doors should be 13 ft 11 in.

Passenger-Coaches vary from 14 to 16 ft in height and from 10 to 11 ft in width. Doors to admit cars should give at least 12 in clearance on each side, and 2 ft overhead.

The Gauge of a railroad track is the distance between the inner sides of the heads of the two rails. The STANDARD GAUGE is 4 ft $8\frac{1}{2}$ in.

Capacity of Freight-Cars. Car-Loads. The capacity of freight-cars, and the minimum car-loads, vary so greatly that no accurate general information can be given. For heavy freight, 25 tons is an average load; for light freight, from 12 to 15 tons; for household goods, from 6 to 12 tons; for lime, 15 tons is about a minimum load; for cement, 20 tons. The minimum car-load, to obtain car-load rates, varies with different roads, and also with the rate made; a low rate is usually made on the basis of a big load. Thirty tons is a good load for heavy freight, and 40 tons is about the maximum, except for special cars. Coal-cars hold from 50 to 70 tons

Street Trolley-Cars are about 8 ft 6 in wide for the car proper, and the steps project about 8 in. Height from track to top of coach, 11 ft 6 in; the trolley-stand is 18 in higher. The length varies, up to 42 ft. Trucks for a 41 ft 6 in car are about 24 ft apart. Wheel-base, 4 ft center to center. Radius of shortest curve in Denver, Colo., 35 ft to midway between rails.

Miscellaneous Dimensions. Horse-Stalls. Width, from 3 ft 10 in to 4 ft or else 5 ft or over; length, 9 ft. The width should never be between 4 ft and 5 ft.

Coal-Bins. Volumes of coal bins may be computed on the assumption that a ton of anthracite coal (2 240 lb) occupies 40 to 43 cu ft, while a ton of bituminous coal occupies 43 to 48 cu ft.

Dimensions of Standard Bowling-Alleys.* For ONE PAIR OF ALLEYS· Room necessary, 83 ft over all; 11 ft 6 in wide, 60 ft from foul-line to head pin, 3 ft for pins to back of alley, 4 ft for pin-pit, 8 in deep in front, 6 in in back; alleys

* Dimensions furnished by The Brunswick-Balke-Collender Company, New York City.

of maple flooring, should extend on and beyond the foul-line 12 ft, and then 4 ft more, making a 16-ft approach to the foul-line for the player to run to deliver the ball. For ONE ALLEY: Same length, 83 ft, width, 6 ft 3¼ in; closer dimensions; beds 42 in, gutters 9 in, division-pieces 2¾ in ball-return 9¾ in.

ONE ALLEY:	In	ONE PAIR OF ALLEYS:	In
Ball-return	9¾	Ball-return	9¾
First-division piece	2¾	First-division piece	2¾
Gutter	9	Gutter	9
Bed	42	Bed	42
Gutter	9	Gutter	9
Second-division piece	2¾	Second-division piece	2¾
6 ft 3¼ in =	75¼	6 ft 3¼ in =	75¼

To the 75¼ in of the PAIR OF ALLEYS, should be added

Gutter	9
Bed	42
Gutter	9
Third-division piece	2¾
	138

Additional room should be provided for the bowlers and spectators as these dimensions are for the alleys only.

Dimensions of a Barrel. Diameter of head, 17 in; diameter at bung, 19 in; length, 28 in; volume 7 680 cu in

Weight of Men and Women. The average weight per person of twenty thousand men and women weighed at Boston, Mass, in 1864, was: men, 141½ lb; women, 124½ lb.

Wooden Flagpoles. For a flagpole, extending from 30 to 60 ft above the roof, the following proportions give satisfactory results The diameter at the roof should be $1/50$ the height above the roof, and the top diameter one-half the lower. To profile the pole, divide the height into quarters; make the diameter at the first quarter above the roof, fifteen-sixteenths of the lower diameter; at the second quarter, seven-eighths, and at the third quarter, three-quarters the lower diameter.

Steel Flagpoles.* Many Departments of Education have abandoned the use of wooden flagpoles and are using steel flagpoles. For an ordinary building, 60 ft in height above the curb, a pole 43½ in height is used, which is sufficient for the tackle of a large or post-flag, for the reason that roof-parapets are very low. Each pole is required to be fitted complete with a cast-iron, galvanized, revolving truck, mounted on crucible-steel pins, the cap beneath it, also, being of galvanized iron. The truck is fitted with two 4¾-in bronze sheaves on Tobin-bronze pins, surmounted with an 8-in 20-oz copper ball, acid-cleaned and painted with four coats of the best English weather-proof sizing, and covered with XXXX leaf-gold. One or more field-joints are permitted in the length of the pole, which are determined according to standard details, the bands being secured to the male tube, and both edges of the inner band and the shoe being machine-beveled to insure a perfect fit. The female tube is drilled and secured to the male shoe with tap-screws of sufficient

* From data compiled by E. S. Hand from notes furnished by C. B. J. Snyder.

strength to carry the upper section of the pole, and the ends of the screws are upset. The exposed ends of the female tube are chamfered and calked tight. A steel collar or band, to receive the copper flashing, is secured to the pole and braced just above the roof-lines.

Dimensions of Schoolrooms. The dimensions of schoolrooms as required by the State Board of Education of the State of Pennsylvania are as follows: "Elementary and grade classrooms should measure 23 ft by 30 ft and be at least 12 ft high. A room 24 ft by 32 ft with a minimum ceiling-height of 12 ft is approved for 40 pupils . . . . Every classroom shall have not less than 15 sq ft of floor-space, and not less than 200 cu ft of air-space per pupil."

Heights of Blackboards in Schoolrooms. The heights from floor to base of blackboard should be as follows:

Primary rooms	1 ft 9 in
Elementary rooms	2 ft 1 in
High-school rooms	2 ft 6 in

Slate blackboards are made 3 ft 6 in, 4 ft and 4 ft 6 in high, 4 ft being a very common and satisfactory height.

School Doors and Stairways. Wardrobes when placed at the end of classrooms should be entered from the classrooms only. Classroom-doors should open into the corridors, so as to afford the teacher control in case of panic. All exit-doors should open out. All stairways should be shut off from corridors by means of self-closing doors, which, together with the stairways and the enclosures, should be of fire-proof materials. Stairways should be of sufficient number to permit of the building being vacated within three minutes from the time a signal is given. This can be effected by allowing a linear width of 4 ft for the first 50 persons and 12 in additional for each 100 persons in excess thereof. No stairway is to be less than 4 ft nor more than 5 ft in width. Corridors should be 9 ft in width. Exits should be planned so as to provide 15 lin ft for the first 500 persons and 6 in additional for each 100 persons in excess thereof. No stairway should have more than 15 steps in any one flight, changes in direction being effected by a square platform and no winders being used. No stair-door or exit-door should open out over a step. Platforms are to be provided for such doors and are to extend at least 1 ft beyond the edge of the door when standing open.

Stairs. The RISE of a stair is the height from the top of one step to the top of the next. The TOTAL RISE is the height from floor to floor. The RUN is the horizontal distance from the face of one riser to the face of the next. RISERS are the upright boards or other materials forming the faces of the steps, and the TREADS are the horizontal pieces or surfaces on which the feet tread. Treads are usually from 1¼ to 1¾ in wider than the run, on account of the NOSING. The height of an individual riser or the RISE of any stairs is found by dividing the TOTAL RISE by the number of risers. The RUN of the stairs may be fixed at will unless the space is cramped, but to secure a comfortable stair the run must bear a certain relation to the rise.

Rules for Dimensions of Treads and Risers. For ordinary use a rise of from 7 to 7½ in makes a very comfortable flight of stairs. For schools and for stairs used by children the rise should not exceed 6 in. Stairs having a rise greater than 7¾ in are steep. The width of the run should be determined by the height of the rise; the less the rise the greater should be the run, and *vice versa*. Several rules have been given for proportioning the run to the rise:

(1) THE SUM OF THE RISE AND RUN should be equal to from 17 to 17½ in.

(2) THE SUM OF TWO RISERS AND A TREAD should not be less than 24 nor more than 25 in.

(3) THE PRODUCT OF THE RISE AND RUN should not be less than 70 nor more than 75.

These rules apply only to stairs with nosings. Stone stairs without nosings should have at least 12-in treads for adults.

Height of Hand-Rail. In dwellings, hotels, apartments, étc., the height of the rail should be about 2 ft 6 in above the tread, on a line with the face of the riser. For grand staircases the height may be reduced to 2 ft 4 in. On steep stairs the height should be from 2 ft 7 in to 2 ft 9 in. The rail should also be raised over winders. On landings, the height of the rail should be equal to the height of the stair-rail, measured at the center of the tread, the usual height in residences being from 2 ft 8 in to 2 ft 10 in.

Sash-Cords.* Until a few years ago, linen or cotton cord only was used for connecting weights with the sashes of double-hung windows, and cord is still more extensively used than either ribbons or chains. For windows of ordinary size a good brand of cord will wear for a long time, and this material will probably never be entirely displaced by metal. "Tests made at the Massachusetts Institute of Technology show that cords wear much longer than chains, though they have less tensile strength. Cords should be smooth and round, so that each strand bears its part of the stress, and well glazed, so that they have a smooth surface and consequently less wear from friction with the wheel of the pulley." It has been found that cord can be braided too hard for durability, yet if it is braided so as to be very flexible it may be so soft that it will stretch and cause great annoyance by permitting the weight to hit the bottom of the weight-box. The architect, however, should always specify the particular BRAND and SIZE of cord to be used, and also the diameter of the pulley. Among the leading brands of sash-cord at present are the Samson Spot,† and the Silver Lake A.‡ These brands are superior to the ordinary braided cords, which are made from inferior yarns to meet the jobbers' requirements for price. In addition to other most excellent qualities, the Samson cord offers an additional advantage that architects will appreciate; it has a colored strand woven through it, which shows in spots on the surface and thus enables one to tell at a glance that no other cord has been substituted. The Silver Lake A sash-cord has the name Silver Lake A branded on every foot of cord; but unless the letter A accompanies the name a second grade of cord is denoted. The marking of the cord by color, or any other device, does not alter the quality of the cord. Special marks may be applied to inferior cords as well as to the best. The following numbers should be specified for the different weights of sash-weights:

Relative Sizes of Sash-Cords, Weights and Pulleys

Size-number.	6	7	8	9	10	12
Diameter in inches	3/16	7/32	1/4	9/32	5/16	3/8
Feet per pound . .	66	55	44	36	27	20
Suitable for weights in pounds up to. . . .	5	12	20	30	40	50
Minimum diameter in inches of pulley allowable	1½	1¾	2	2¼	2½	3

* The following notes, relating to Sash-Cords, Sash-Chains, Sash-Ribbons, Sash-Weights and Sash-Balances, are condensed from articles by the late Professor Thomas Nolan.

† Manufactured by the Samson Cordage Works, Boston, Mass.

‡ Manufactured by the Silver Lake Company, Newtonville, Mass.

* The editor is indebted to T Z. Talley for the calculations and arrangement of this table.

For hanging sashes weighing over 40 lb, only the largest size of Samson or Silver Lake A cord, or some form of sash-chain or sash-ribbon, should be used, and the pulleys should be selected to fit the çord or chain. A guarantee that the cord will last at least twenty years may be had from either of the manufacturers mentioned above. The Samson wire-center sash-cord has recently been put on the market. This is really a metal sash-cord protected by a braided-cotton surface which acts as a noiseless cushion. It is claimed that it harmonizes with the window-finish and that it has greater durability than other sash-cords or metal devices. The standard color is that of dark mahogany, but this cord is made to order for large buildings in other colors to match the finish.

Sash-Chains. Of several styles of sash-chains on the market, the style most largely used is the flat-link chain. This chain is made either of steel, or of bronze composed of 95% copper and 5% of tin. For suspending very heavy sashes, doors and gates, a cable-chain has been extensively used. Star sash-chain is made of bronze-metal. The manufacturers of the Norris sash-pulley claim that a riveted chain that has joints only one way is almost sure to break when even slightly twisted, and that it is better to use two chains of the link-pattern running side by side over the same pulley. The strongest sash-chains are of steel, made rust-proof by the hot-galvanizing process, and electro-copperplated to give a bronze finish; and of a bronze-mixture which looks like copper, but is tougher and harder. One firm claims that its galvanized-steel sash-chain is from 11 to 45% stronger than any bronze or copper sash-chain and that it will resist fire for a much longer period. The tensile strength of their chain varies from 475 to 850 lb, according to the weight used.

Sash-Ribbons. These are sometimes used in hanging the sashes of buildings The ribbons are made of steel and aluminum-bronze or of some mixture of aluminum, and in 3/8, 1/2, 5/8, 3/4 and 7/8-in widths. They are claimed to be practically indestructible, but according to one series of tests it would appear that in some cases they do not wear as long as sash-cords or sash-chains. Some people object that the ribbons snap against the pulley-stiles, when the sash is raised or lowered, and thus make considerable noise. The 3/8-in ribbon may be used for a sash weighing up to 100 lb and requiring 50-lb weights. Sash-ribbons are now manufactured by a number of firms which also make the necessary attachments for weight and sash. For the best working of windows hung with ribbons, pulleys of the following sizes should be used:

For sashes weighing not over 40 lb,	2 in
For sashes weighing not over 60 lb,	2 1/4 in
For sashes weighing not over 100 lb,	2 1/2 in
For sashes weighing not over 150 lb,	3 in
For sashes weighing not over 250 lb,	3 1/2 in
For sashes weighing not over 300 lb,	4 in
For sashes weighing not over 350 lb,	4 1/2 in

Comparative Strength of Sash-Cords and Chains. The comparative strength and durability of sash-cords and chains have been determined by careful tests, but there is a great variation in both cases, due partly to variation in material, but principally to the relative sizes of the chain and pulley or cord and pulley. The cords or chains may be too light for the weights used, or the pulleys too small in diameter to carry the cord without undue bending. The pulleys may also have too narrow a groove or an uneven groove with sharp edges which cut the cords. The larger the diameter of the pulley, the longer the wear.

Tests* on Wire-Center Sash-Cord and Bronze Sash-Chains. The cord tested was size No. 8, ¼-in diam, Samson solid braided cotton cord with steel-wire cable center, ⅟₁₆ in in diam. The chains tested were of two different makes of bronze, size No. 2, purchased in the open market as typical bronze sash-chains, each recommended by a reputable dealer as the proper chain for use with a 25-lb window-weight. The tests for the better of the two chains are those given. Durability-tests were made by raising and lowering a 25-lb weight over a 2-in pulley, each movement corresponding to once opening and shutting a window. The cord was tested over the regular round grooved pulley ordinarily used for cords, and the chains were tested over the combination grooved pulley usually furnished for sash-chains. For the fire-tests the cords or chains were hung through an asbestos box in which a Bunsen flame under pressure was applied to all alike, the temperature being about 2 200° F. A 25-lb weight was attached in each case to keep the cord or chain under the same tension. The wire-center cord took about twice as long to burn through and wore about seventeen times as long as the bronze chain.

Weights of Sashes and Glass. In figuring the weights of windows, the weight of the glass may be taken at 3½ lb per ft for plate glass, 1⅛ lb for double-strength glass and 1 lb for single-strength glass. For the weight of the wooden sash, add together the height and width, in feet, of each sash, and multiply by 2.1 for 2¼-in sash, by 1⅔ for 1¾-in sash and by 1⅓ for 1⅜-in sash. These values are sufficiently accurate for determining the size of sash-cords and pulleys, but the weights should be determined by weighing each sash after it is glazed, as the weight of the glass varies considerably.

Iron Sash-Weights. The weights ordinarily used for balancing windows are made of cast iron, in the form of solid cylinders from 1⅜ to 2⅛ in in diameter, and from 7½ to 31 in long, with an eye cast in the upper end of each. The lengths vary with the weights, which are from 2 to 25 lb. Flat weights, which usually are called for in the Philadelphia and some other markets, are from 6

* Made at the Massachusetts Institute of Technology, May, 1914, by Professor E. F. Miller.

to $34\frac{1}{2}$ in long, from 2 to 30 lb in weight, and from $1\frac{1}{4}$ by $1\frac{5}{8}$ to $1\frac{5}{8}$ by $2\frac{1}{4}$ in in cross-section. In ordering sash-weights the number of pounds of each weight, and the sections and lengths of the boxes in which the weights will work, should be given. Ordinary weights have very rough eyes for the sash-cords. There are a few manufacturers in the East who make weights with a patent eye that will not cut the cord. A sectional sash-weight made with a well-designed hooking-device which has given satisfaction, is said to be one of the best on the market. Usually from three to six sections are required on each side to balance a sash properly. If the hooking-device fails near the top the upper sash cannot be closed and if at the bottom the window cannot be opened. It is then necessary to open the weight-box and rehang the sections before the window can be operated. In theory, sectional weights are ideal; in practice, however, they are not considered as satisfactory as solid weights. The Brown sectional weights are made $2\frac{1}{4}$ by $2\frac{5}{8}$ in and in weights of 6, 7, 8, 9 and 10 lb. They are made of both cast-iron and lead. It frequently occurs after a contract is let, that the glass is changed from double-thick to plate or prism glass. This means increased weight; but the length of the sash-weight cannot be increased and it, therefore, becomes necessary to increase the area of its cross-section. If the weight-box is detailed to take the regular round sash-weight, its general construction will be such that it will take a 2-in round sash-weight, but not a 2-in square sash-weight. This difficulty can be avoided by a little thought at the start. An added depth of $\frac{1}{4}$ in in the weight-box permits the use of a rectangular cast-iron sash-weight. The Sanborn sectional sash-weight is intended for use in large buildings of heavy construction. Because of the lack of uniformity in the weight of plate glass the required weights of sash-weights cannot be accurately determined previous to the hanging of the sashes. By the use of a sectional sash-weight, combinations of units can be made up to suit the requirements. The units are made square or rectangular in section in order to secure a maximum weight with a minimum length. An opening of 12 in in the side of the pocket is sufficient for hanging the largest unit. These units are manufactured in standard sizes to meet the general conditions found in the building trades.

Lead Sash-Weights. It often happens that for wide and low windows the weights if of iron would be so long that they would touch the bottom of the pocket before the bottom sash was fully raised. In such cases lead weights are usually resorted to, lead being 80% heavier than cast iron. By casting the weights square in section, whether of iron or lead, a considerable saving can be made in the lengths. One sash-weight manufacturer makes a specialty of compressed-lead sash-weights, with wrought and malleable-iron fastenings, centered so that the weights hang perfectly plumb; and when lead weights are necessary the architect will do well to specify the weights made by this company. These weights are made under hydraulic pressure, by which greater smoothness, solidity and density of metal is secured than is possible by the casting-process. A wrought-iron rod is run through the center, to which are securely attached the malleable-iron fittings. In hanging the sashes the weights for the upper sash should be about $\frac{1}{2}$ lb heavier than the sash, and for the lower sash, $\frac{1}{2}$ lb lighter.

Sash-Balances. Several devices have been patented for balancing sashes by means of springs instead of weights. The sash-balance consists of a drum on which the ribbon is wound, and which contains a coiled-steel clock-spring. immersed in oil; the spring sustains the weight of the sash. The common type very much resembles in outward appearance the ordinary sash-pulley, and is

applied practically the same way; the ribbons, which are made usually of aluminum-bronze, are attached to the sashes in the same manner as cords when weights are used. While the sash-balance in its best form works very satisfactorily, it will probably never entirely supplant the weight and axle-pulley for ordinary windows. There are many windows, however, for which sufficient pocket-room for weights cannot be obtained without spoiling the effect desired or narrowing the glass, as in some bay windows, or where it is undesirable to break the frame into the brick jamb. In such cases the sash-balance is almost invaluable. For hanging the glass doors of show-cases, sash-balances are usually preferable to weights Sash-balances are made in both side and top-patterns, but the former are recommended wherever there is room at the side of the frame for the depth of mortise required. For windows of the sizes usually found in residences, the depth of the sash-balance measured from the face of the pulley-stile will vary from 3 to 4 in; this can be provided for usually by cutting a hole, if necessary, in the masonry or studding back of the frame. As sash-balances require only a plank frame, the consequent reduction in the cost of the frame offsets the extra cost of the balance. In remodeling old buildings which have plank frames without weights, sash-balances are found to be a great convenience, since they can easily be inserted in the old frames. An advantage which all spring-balances possess is that they act most strongly when the sash is down, and so enable one to raise a binding window more readily than if it were hung with weights; while when the sash is up the springs barely suffice to hold it in position, and do not offer resistance to drawing it down. Of the various sash-balances on the market, the Pullman and the Caldwell are extensively used, and are undoubtedly reliable. The Pullman Unit sash-balance has been on the market many years and has proved satisfactory. These balances are now made with uniform-size face-plates for the various weights of sash with which they are to be used, and thus make it possible to have all mortises for the balances cut at the mill, as is now done for the regular cord-pulleys. The Caldwell sash-balance, both top and side-types, is much used by the United States Post Office and Navy Departments It is used also by the leading car-builders. The springs are made of high-grade cold-rolled tempered-steel wire, a material similar to that used for clock-springs The manufacturers guarantee these sash-balances for from ten to fifteen years.

Seating-Space in Churches and Theaters. The minimum spacing for pews, back to back, is 30 in. This spacing is fairly comfortable for occupants, but is a little cramped for persons passing by others into or out of the pews. A spacing of 32 in is to be preferred, and if there is abundance of room, the spacing may be made 33 in. Anything over 33 in is a waste of room. A space of 18 in in the length of the pew is considered a SITTING.

Opera or Theater-Chairs are made 19, 20, 21 and 22 in wide, center to center of arms, and in arranging them in rows where the aisles converge, the ends are brought to a line on the aisles by using a few chairs that are either narrower or wider than the standard width. For churches, a standard width of 20 in is the least that is desirable. For theaters, 21 or 22-in chairs are commonly used in the parquet, 20 or 21-in in the dress-circle, and 20 and 19-in in balcony and gallery, although there is no accepted rule in this respect. On account of the seat-lifting, opera or theater-chairs may be comfortably spaced 31 in, back to back, and this is the usual spacing in halls and churches In theaters the chairs are usually set on steps. In the upper gallery these steps should not be more than 30 in wide; in the balcony they are usually made either 30 or 31 in

wide, and in the parquet, 31 or 32 in wide. As a rule the higher-priced seats are more commodious than the lower-priced.

Estimating Seating Capacity. The actual seating capacity of theaters and audience-rooms can be determined only by drawing the seats to an accurate scale, on the floor plan, and then counting the number of chairs, or measuring the linear feet of pews.

Approximate Seating Capacity. For approximate purposes the seating capacity or required size of room may be determined by allowing from 7 to 8 sq ft to each seat, or sitting, when on a curve, and from 6 to 7 sq ft to each sitting when in straight rows, the smaller number being used only for large rooms. This allows for aisles and pulpit-platform. For small concert-halls and narrow rectangular rooms, 6 sq ft per sitting will usually be sufficient allowance, provided only that the actual floor-space utilized for seats and aisles is considered. A reasonable minimum area per seat, omitting aisles, is about 18 in by 30 in, 540 sq in or 3.8 sq ft.

Capacity of Several of the Older Cathedrals, Churches, Theaters and Opera-Houses *

* The above table of seating capacities of some of the earlier churches and theaters is retained for purpose of comparison. So many important structures of these types have been erected in recent years in the larger cities of the world, or are now in process of erection, that it has been found impossible to make any list that would be and would remain, for any length of time, complete.

* From the curtain or back line of proscenium opening.
† Measured from stage to center of ceiling
‡ To the "gridiron" or rigging-loft
§ As remodeled in 1893.
¶ The plan of this theater is in the shape of a horseshoe.

Notes on Theater-Dimensions.* "The utmost distance from the front of the stage to the rear ought not to exceed 75 ft, or the limit the voice is capable of expanding in a lateral direction."

"Measured from the curtain-line, the San Carlo Theater in Naples is 73 ft; the theater at Bologna, 74 ft. Of the London theaters, the Adelphi is 74 ft, Covent Garden 80 ft, the Gaiety 53 ft 6 in, Lancaster 58 ft 4 in, Marylebone 74 ft and the Globe 47 ft 6 in."

* From The Planning and Construction of American Theatres, by Wm. H. Birkmire.

The width of the ideal theater, between inside walls, should be from 70 to 75 ft, and "the ceiling should be from 55 to 65, or even 70 ft above the stage-level."

"The depth of the parquet-floor at the orchestra-rail is governed by the stage level, and is generally from 3 ft 6 in to 4 ft 3 in below the stage. A depth of 3 ft 9 in is a good height, as it fixes the eye of the spectator 5 in above the stage-level."

"The height of the stage, that is, from the floor to the bottom of the 'gridiron' or rigging-loft, should be 2 or 3 ft over twice the height of proscenium opening, in order that the fire-curtain may be raised the full height of the opening." There should be a height of 7 ft above the gridiron to enable the fly-men to adjust their ropes with facility.

ATHLETIC FIELDS AND COURTS

General. The information concerning the dimensions of athletic fields and courts is presented as an aid to architects in designing gymnasiums and playing-fields. All data in this section have been compiled, by permission, from various volumes of Spalding's Athletic Library.

Baseball. Fig. 1 is a diagram showing the official measurements for laying out a baseball field, taken from Official Baseball Rules, adopted by the National and American Leagues and the National Association of Professional Baseball Leagues. The following excerpts are taken from the Official Baseball Rules.

The Ball Ground. The ball ground must be enclosed.* To obviate the necessity for ground rules, the shortest distance from a fence or stand on fair territory to the home base should be 235 ft and from home base to the grandstand 60 ft.

To Lay off the Field.† To lay off the lines defining the location of the several bases, the catcher's and the pitcher's position and to establish the boundaries required in playing the game of baseball, proceed as follows:

DIAMOND OR INFIELD.‡ From a point, A, within the grounds, project a straight line out into the field, and at a point, B, 124 ft from point A, lay off lines BC and BD at right-angles to the line AB; then, with B as a center and 63.63945 ft as a radius, describe arcs cutting the lines BA at F and BC at G, BD at H and BE at I. Draw lines FG, GI, IH, and HF, each 90 ft in length, which said lines shall be the containing lines of the diamond or infield. See Fig. 1.

Football. Fig. 2 is a diagram of the field of play as recommended by the Football Rules Committee. This committee is appointed by the National Collegiate Athletic Association.

Soccer Football. The following excerpts are taken from Laws of the Game, as promulgated by the National Collegiate Athletic Association, and as adopted by the Intercollegiate Soccer Football Association of America.

Dimensions of the Field. See Fig. 3. The dimensions of the field of play shall be: maximum length, 120 yd; maximum breadth, 75 yd; minimum

* Enclosure applies to professional leagues.

† For further detailed information concerning the laying out of a baseball field see Official Baseball Rules.

‡ If it is possible to do so, have the home plate due north and the pitcher's plate due south.

length, 100 yd; minimum breadth, 55 yd. The field of play shall be marked by boundary-lines. The lines at each end are the goal-lines and the lines at each side are the touch-lines. The touch-lines shall be drawn at right-angles with the goal-lines. A flag with a staff not less than 5 ft high shall be placed at each corner. A half-way line shall be marked out across the field of play.

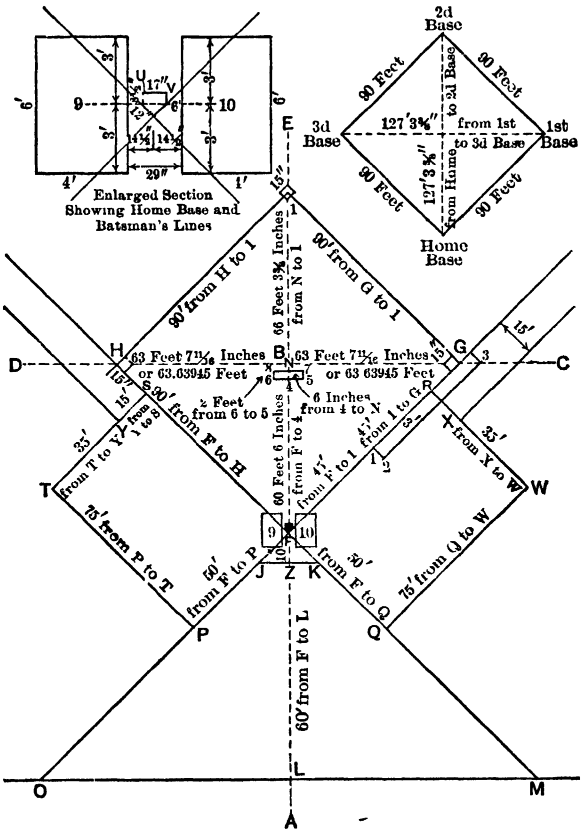

Fig. 1. Measurements for Laying Out a Baseball Field

The center of the field of play shall be indicated by a suitable mark, and a circle with a 10-yd radius shall be made around it. The goals shall be upright posts, fixed on the goal lines, equidistant from the corner flag-staffs, 8 yd apart, with a bar across them 8 ft from the ground. The maximum width of the goal-posts and the maximum depth of the cross-bar shall be 5 in. Each goal shall be provided with regulation goal-nets. Lines shall be marked 6 yd from each goal-post at right-angles to the goal-lines for a distance of 6 yd, and

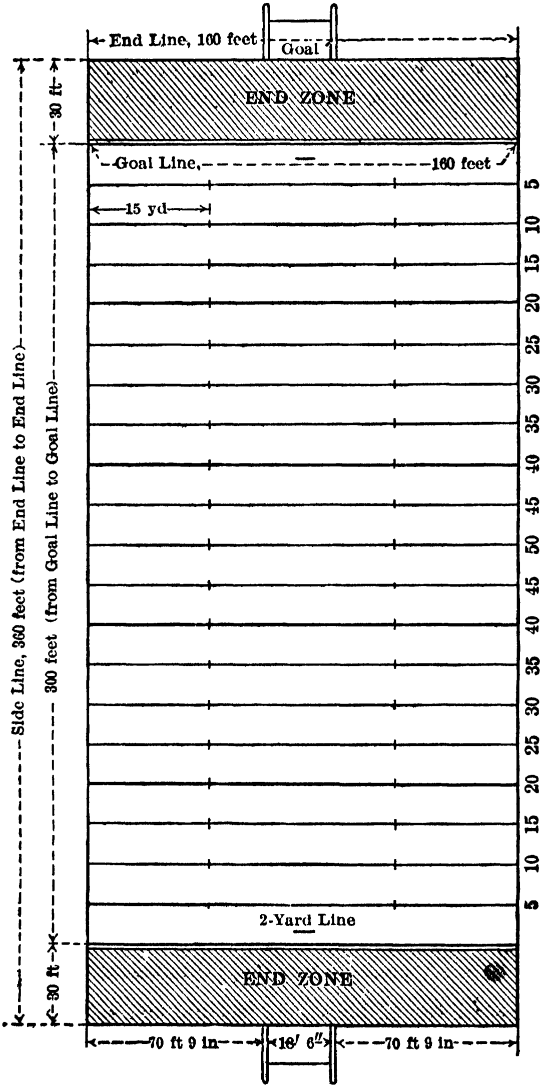

Fig. 2. Diagram of a Football Field

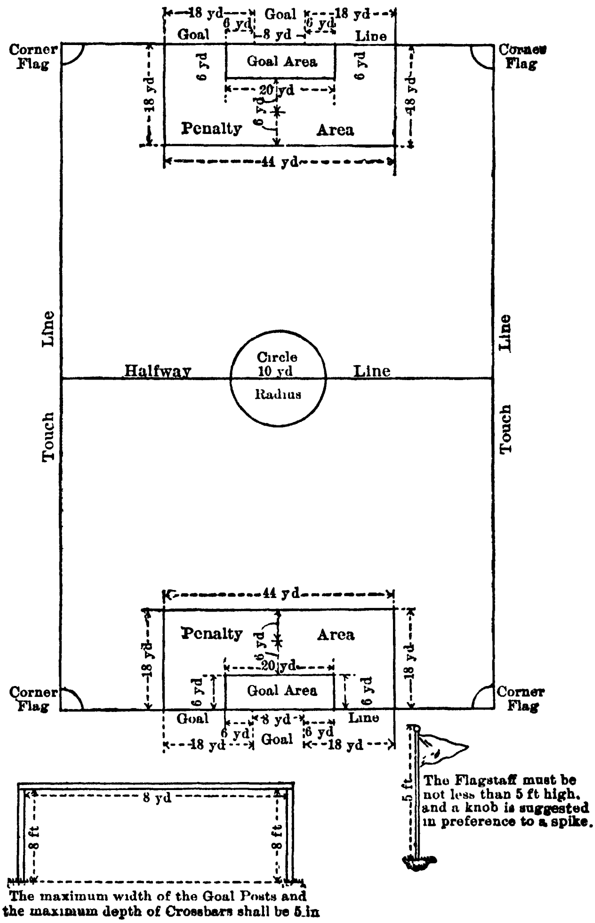

Fig. 3. Diagram of a Soccer Football Field

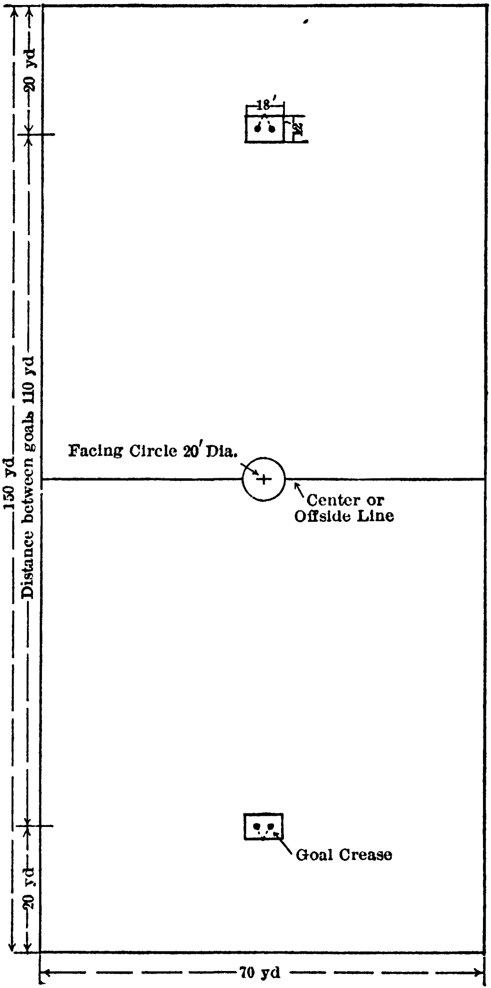

Fig 4 Diagram of a Lacrosse Field

Outer lines should be marked in white. A barrier fence to retain the ball should, if possible, be located a short distance beyond the boundary lines. Dimensions shown are minimum; for maximum, see text.

these shall be connected with each other by a line parallel to the goal-lines: the space within these lines shall be the goal area. Lines shall be marked 18 yd from each goal-post at right-angles to the goal-lines for a distance of 18 yd, and these shall be connected with each other by a line parallel to the goal-lines; the space within these lines shall be the penalty area. A suitable mark shall be made opposite the center of each goal, 12 yd from the goal-line; this shall be the penalty-kick mark.

Lacrosse. See Fig. 4. The following excerpt is taken from Lacrosse Rules, approved by the Executive Committee of the United States Intercollegiate Lacrosse Association. Each goal shall consist of two poles 6 ft apart, and 6 ft high out of the ground, joined by a rigid top cross-bar. The poles must be fitted with a pyramid-shaped cord netting (as shown in sketch) of not more than 1½-in mesh, which pyramid shall extend and be fastened to a stake in the ground at a point 7 ft back of the center of the goal, and the said netting shall be so made as to prevent the passage of the ball put through the goal from the front, and the bottom of the netting must be held close to the ground with tent-pegs or staples. The goals shall be placed 110 yd from each other, with from 20 to 35 yd of clear playing space behind each goal. In matches, they must be furnished by the home club. The width of the field shall be at least 70 yd and not more than 85 yd. The boundaries of the field shall be marked with white lines, and a white line shall be drawn through the center of the field perpendicular to the side-lines.

Field Hockey. See Fig. 5. The instructions given here for laying out a field for field hockey are taken from Learning to Play Field Hockey, Spalding's Athletic Library. The ground should be 100 yd long, and not more than 60 yd, and not less than 55 yd wide. Where possible, always have the ground 60 yd wide. In marking out, note that flag-posts are to be placed at *each corner*, on the junction of the goal and the side-lines. In other cases they are to be one yard outside the touch-line. The 25-yd line must not be fully drawn, but only its extremities (7 yd only to be marked at each end). It is advisable to mark with short lines 3 yd either side of each corner flag, and also 5 yd and 10 yd from each goal-post. The 3-yd marks are where corners are hit from on either side of the flag-post, which may be moved if it impedes the player. The 10-yd marks are the nearest point to the goal-posts from which a penalty corner may be hit. The 5-yd marks are to show the defenders their distance from the strikers of a penalty corner, for no player may stand within 5 yd of it. The 5-yd line, extending the full length of the ground parallel to the touch-line, can be marked either all the way or at intervals of a yard or so. At the roll-in from touch no player may be within this line and the touch-line.

Ice Hockey. See Fig. 6. Instructions given here are taken from Official Ice Hockey Rules, as recommended by the Rules Committee of the National Collegiate Athletic Association. The rink, or playing surface, should be a clear field of ice at least 160 by 60 ft and not greater than 250 by 110 ft. A size of 190 by 85 ft, with rounded corners of 15-ft radius, is recommended.

Lawn Tennis. See Fig. 7.

Basket-Ball. See Fig 8. The dimensions given here are taken from Official Basket-Ball Rules, as adopted by the Joint Basket-Ball Rules Committee. The playing court shall be a rectangular surface free from obstructions and shall have maximum dimensions of 94 ft in length by 50 ft in width and minimum dimensions of 60 ft in length by 35 ft in width. The following dimen-

sions are considered ideal for teams whose players are of the age indicated for each group:

Elementary-school age	40 by 60 ft
High-school age	48 by 75 ft
College age	48 by 84 ft

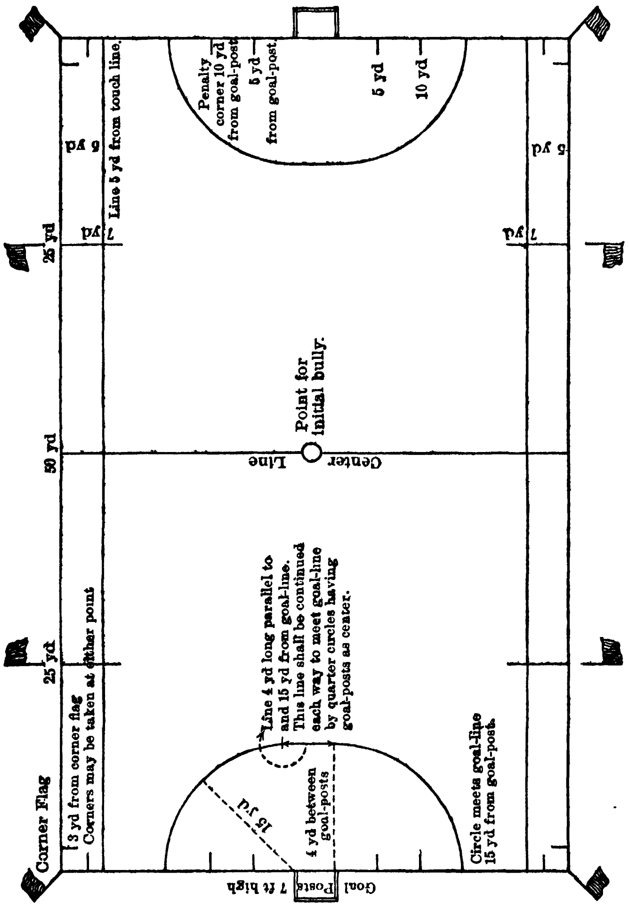

Fig. 5. Diagram of a Field for Field Hockey

These are the dimensions for the playing court only. In planning gymnasiums at least 10 additional feet should be provided on each side and each end.

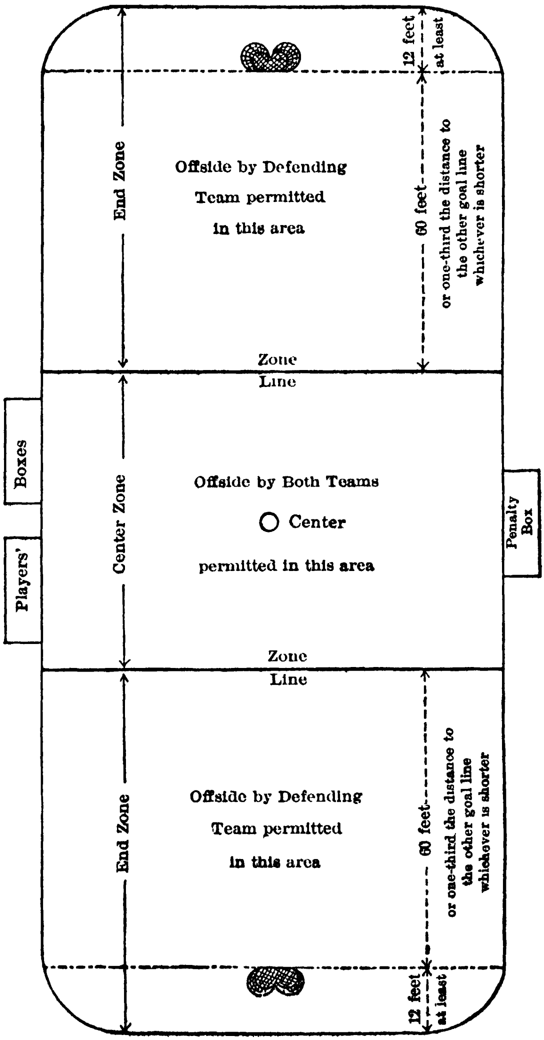

Fig. 6. Diagram of a Rink for Ice Hockey

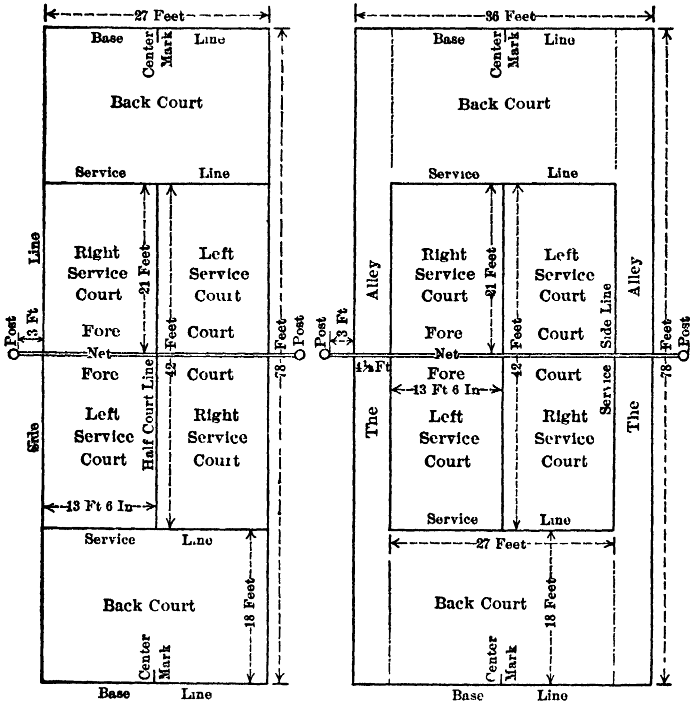
Backboards must be provided, the dimensions of which shall be 6 ft horizontally and 4 ft vertically. These backboards shall be made of plate glass or wood, or of any other material that is flat and rigid. The faces of the backboards shall be painted white. The backboards shall be located in a position at each end at right-angles to the floor, parallel to the end lines, and with their



The Singles Court

The above diagram shows a court which is marked for the singles game only. The adjoining diagram shows how a court may be marked for both singles and doubles.

The Doubles Court

The service side lines should extend to the service lines only. The dot-and-dash lines show how the service side lines would be extended to the base lines in a court marked for both the singles and doubles game.

Fig. 7. Diagram of Lawn Tennis Courts

lower edges 9 ft above the floor. Their centers shall lie in the perpendiculars erected at the points in the court 2 ft from the midpoints of the end-lines. The faces of the backboards shall be 15 ft from the far edges of the free throw lines.

The ring, 18 in inside diameter, shall be rigidly attached to the backboard; it shall lie in a horizontal plane 10 ft above the floor and shall be equidistant from the two vertical edges of the backboard. The nearest point of the inside edge of the ring shall be 6 in from the face of the backboard.

Women's Basket-Ball. See Fig. 9. The following dimensions are taken from The Official Basket-Ball Guide for Women, Spalding's Athletic Library. Maximum court, 100 ft by 50 ft; use three divisions. Minimum court, 50 ft

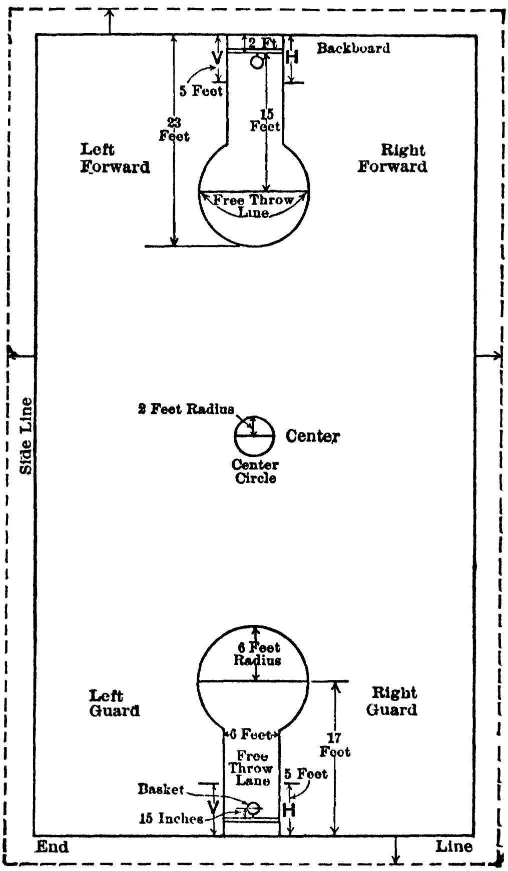


Fig. 8. Diagram of a Basket-Ball Court

For dimensions of ideal-sized courts, see text. A minimum distance of 3 ft., free of all obstructions, should be allowed outside of boundary lines, as indicated by dotted lines.

by 25 ft; use two divisions. Regulation-size court, 90 ft by 45 ft for college players; 70 ft by 35 ft for high-school players; use three divisions. The face of the backboard should be 2 ft from the end-wall; but on short courts, when the backboard is placed against the wall, there shall be an end-line, the inner

edge of which is 2 in out from the wall. On narrow courts when the playing court is the full width of the floor there shall be a side-line, the inner edge of which is 2 in out from the wall. The positions of the players are determined

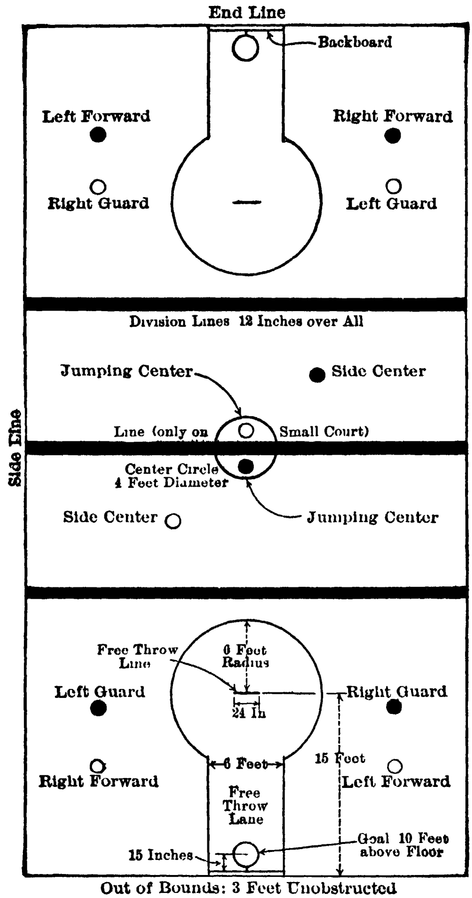

Fig. 9. Diagram of a Women's Basket-Ball Court

by standing with backs toward the goal that is being defended and facing the goal that is being attacked.

Volley-Ball. See Fig. 10. The diagram and dimensions here given are taken from Official Volley-Ball Rules adopted by the National Amateur Athletic Federation. The playing surface shall be a rectangular court 60 ft

long and 30 ft wide, including outer edge of lines, free from obstructions and having a height of 15 ft or more which is free from apparatus or other obstruc-

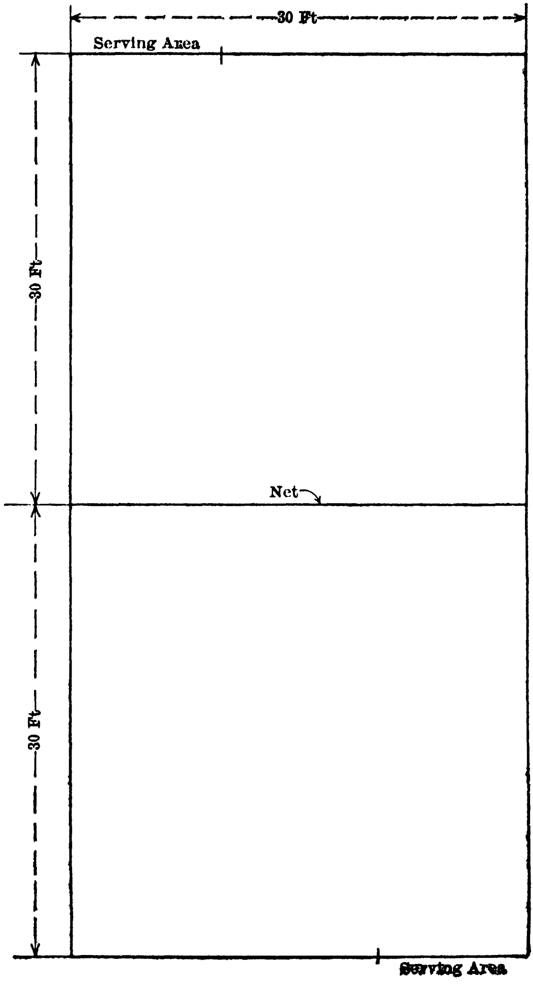

Fig. 10. Diagram of a Volley-Ball Court

tions or projections. The size of the court may be modified for either indoor or outdoor informal games, to accommodate larger or smaller groups to suit local requirements. The court shall be bounded by well-defined lines 2 in

in width, which shall be at every point at least 3 ft from walls or any obstructions. The lines on the short sides of the court shall be termed the end-lines; those on the long sides the side-lines. A center-line, 2 in in width, shall be drawn on the court immediately beneath and parallel to the net.

American Handball. See Fig. 11.

Four-Wall Handball. See Fig. 12. These dimensions are taken from Official Four-Wall Handball Rules of the Amateur Athletic Union of the United States. Standard courts shall have four walls and a ceiling, shall be 22 ft in width, 46 ft in length and 22 ft in height.

The building and use of standard courts is advised, but championships may be held on courts of other sizes as approved by the Handball Committee.

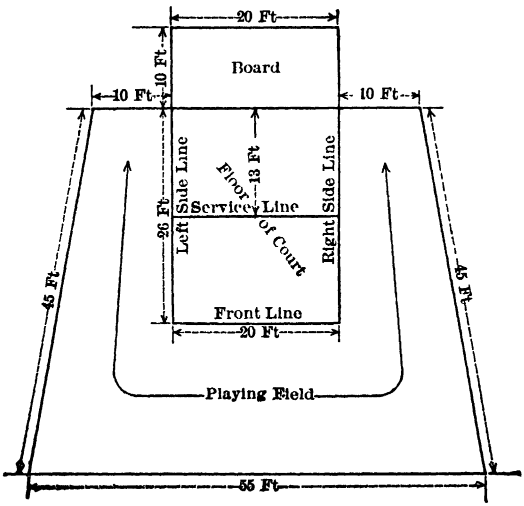

Fig. 11. Diagram of an American Handball Court

Squash Rackets. The following data have been obtained from A. G. Spalding & Bros. The size of the court shall approximate as closely as possible 18 ft 6 in by 32 ft. The service-line on the front wall shall be 6 ft from the floor; the telltale shall be 17 in from the floor and may be made of sheet metal protruding $1\frac{1}{2}$ in from the wall. The line on the back playing wall shall be 6 ft 6 in from the floor, and a strip of wire netting shall be stretched above this line several inches from the floor. The service-court line shall be 9 ft 10 in from the back wall, and the service box shall be 4 ft 6 in in radius, in the shape of an arc of a circle. Halfway from the two side-walls a line shall be drawn from the service-court line to the back-wall, dividing the two service-courts; the general color of the court shall be white. The over-all height of the court shall be from 14 to 22 ft to allow for light. There is no regulation side-wall height, therefore no side-wall line.

Wrestling. See Fig. 13. The following excerpt is taken from National Collegiate Athletic Association Wrestling Rules. The area of the mat shall not be

less than 20 ft by 20 ft, and this dimension shall be considered the standard size, when ropes are used. When ropes are not used a 24 by 24-ft mat shall be considered standard. Whenever possible it is recommended that a "roped-in" area be used in accordance with the following specifications. Three 1-in ropes shall be tightly stretched 2 ft, 3 ft and 4 ft, respectively, above the mat. These ropes shall extend in from four supporting posts, which shall be placed at least 18 in back from the corners of the ring. Cotton ropes are recom-

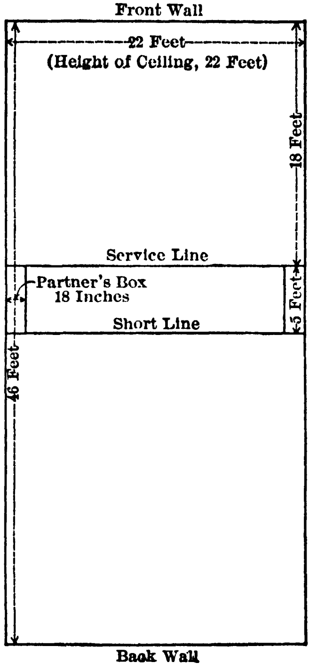

Fig. 12. Diagram of an Official Four-Wall Championship Handball Court

mended, but if manila or sisal ropes are used they must be wrapped with bunting or other soft material to avoid " rope burns." To prevent the spreading of ropes during bouts, they shall be securely fastened together by twelve vertical $\frac{3}{8}$-in ropes, three of which shall be placed equidistant on each side of the ring.

Boxing. The following requirements for equipment are taken from the National Boxing Association Rules.

Ring to be not less than 18 nor more than 20 ft. square * within the ropes, the ring floor to extend beyond the ropes a distance of not less than 18 in.

* The Amateur Athletic Union Boxing Rules call for a ring "not less than 16 ft nor more than 20 ft square . . . The floor of the ring shall extend beyond the lower rope for a distance of not less than 2 ft."

The ring posts shall be not nearer to the ring ropes than 18 in. The ring floor shall be padded with felt, matting or other soft material to a thickness of not less than 1½ in extending over edge of ring platform with a top covering of canvas, duck or similar material tightly stretched and laced to ring platform. Material that tends to gather in lumps must not be used.

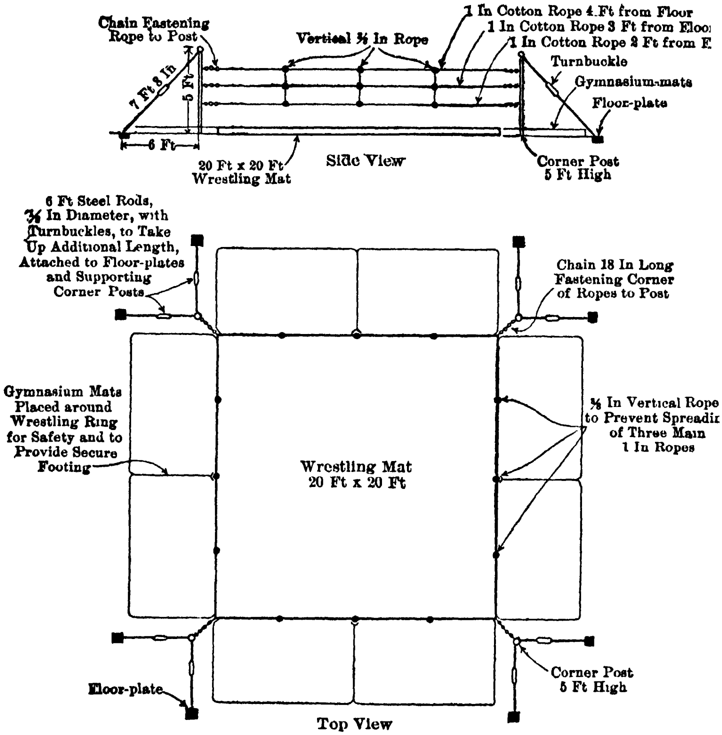

Fig. 13. Diagram of a Wrestling Mat

Height of Ring shall be not more than 4 ft above the floor of the building, and shall be provided with suitable steps for the use of the contestants. Ring posts shall be made of metal not more than 3 in in diameter, extending from floor of building to height of 58 in above ring floor.

Ring Ropes shall be three in number, not less than 1 in in diameter; the lower rope 18 in, the second rope 35 in, and the third rope 52 in above the floor. Ropes shall be wrapped in soft material.

Roque. See Fig. 14.

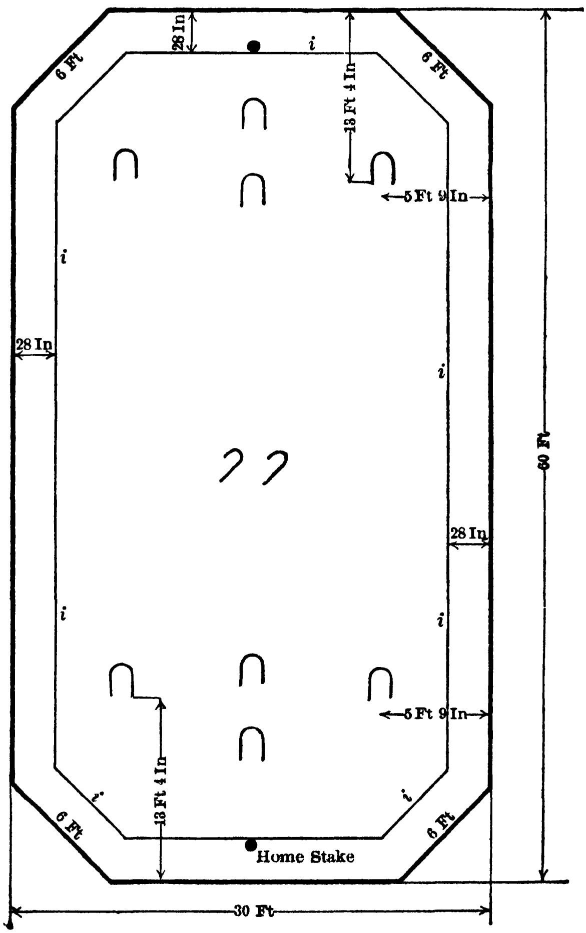

Fig. 14. Diagram of a Roque Court

Badminton. See Fig. 15.

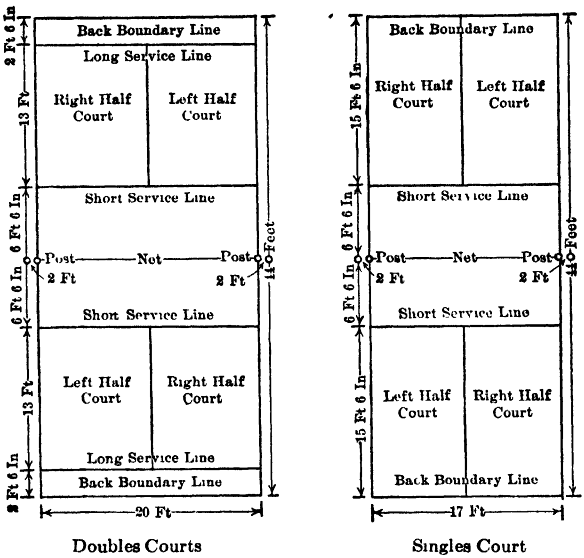

Fig. 15. Diagram of Badminton Courts

The posts shall, if practicable, be placed on the Side Boundary Lines, otherwise at any distance not exceeding 2 ft outside the said lines. On the Singles Court the Back Boundary Lines become the Long Service Lines.

MAIL-CHUTES

General Description. This system of mailing letters by means of a specially constructed chute connected with the receiving-box at the bottom, has come into such general use in public buildings, office-buildings, apartment-houses and hotels, that the restrictions affecting the same and what is required in the way of preparation should be known to architects. The system is installed by the patentees, under regulations of the Post-Office Department governing its construction and location, and for this reason it is well to consult the makers * before permanently locating the apparatus on the plans. It may be placed in any building of more than one story, used by the public, where there is a free delivery and collection-service, in the discretion of the local postmaster; subject to whose approval the contracts are made.

The Chute and Receiving-Box. The chute is required to be made with a removable front and a continuous, rigid, vertical support is absolutely necessary. It must be of metal, its front must be of plate glass, and it must bear the insignia prescribed by the department; and the whole apparatus, when erected and the Government lock put on the box, passes under the exclusive

* The Cutler Mail Chute Company, Rochester, N. Y.

care and control of the Post-Office Department, and the chutes become a part of the receiving-boxes. These boxes may be of various patterns and highly ornamental and are furnished by the makers in connection with the chutes. The work of preparing a rigid support for the chute and cutting and finishing the openings in the floors is of the utmost importance, and details showing the usual arrangements are always given.

Preparatory Work. The requirements for what the manufacturers call PREPARATORY WORK include a flat, vertical, continuous surface not less than 10½ in wide, extending from the floor of the ground-story to a point 4 ft 6 in above the finished floor in the top story, and an opening in each floor directly in front of and centered upon this surface. These openings are neatly finished,

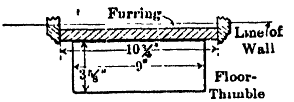

Fig. 1. Wooden Support for Mail-chute

Fig. 2. Steel Support for Mail-chute

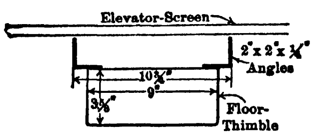

Fig. 3. Alternate Steel Support for Mail-chute

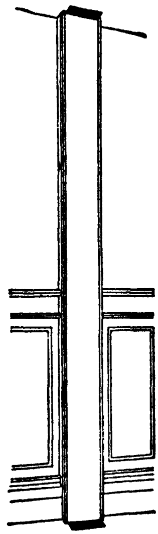

Fig. 4. Preparatory Work Complete for Mail-chute

and their size and shape determined by setting in them thimbles of iron which are furnished and delivered by the patentees as part of their contract. In ordinary installations a casing of wood, suitably molded and finished to match the trim of the building, answers every purpose. Such a casing is shown in plan, Fig. 1, with the opening finished by the iron thimble. In buildings, or sometimes in a few stories, where a more elaborate finish is desired, marble is substituted for wood, the form and construction of the casing being adapted to the material, but of course without disturbing the size and form of the front surface. Steel angles are used where the use of wood is objected to, or where it is necessary to run the chute in front of an elevator-screen, or in other locations where a solid wall is not available to support the casing. Steel square-root angles, 2 by 2 by ¼ in in section, are generally used, and set as in Fig. 2,

but sometimes, where it is desirable to fill up the space between them and the elevator-screen, they are reversed, as in Fig. 3. The angles are usually bolted to the beams, and in any case must be straightened so that they are without twists or kinks, and the surface which receives the mail-chute plumb and flush in all stories. Fig. 4 gives a general view of the mail-chute casings and floor-openings ready to receive the chutes themselves. This work of preparing the building, except the cutting or leaving ready the necessary openings in the floors, is now usually included in the mail-chute contract, as it has been found for many reasons undesirable to separate it. The necessary openings in floors, and all patching around such openings, should be included in the mason's or other proper specifications.

Essential Points to be remembered are (1) that no bends or offsets can be made, a vertical fall being absolutely essential, and (2) that the entire apparatus must be exposed to view and must be accessible, that is, it is not permitted to extend the work behind an elevator-screen or partition or through any part of the building except a public corridor.

REFRIGERATORS *

General Requirements. The following information is given as a guide to architects in providing for refrigerators in large residences, hotels, clubs, hospitals and other institutions. Consultation with a reliable refrigerator-builder, however, is always desirable before deciding upon spaces to be occupied by refrigerators, refrigerating-rooms, etc., as a satisfactory refrigerator cannot be adapted to a badly proportioned space.

Residence-Refrigerators. Care should be taken to select a refrigerator which is simple in operation and easily cleansed, as modern sanitary science has traced much illness to faulty refrigeration. Thorough insulation is an important feature in a refrigerator, as upon this depends economy in the use of ice and the securing and maintaining of the low temperature necessary to the proper preservation of food. Fig. 1 shows a kitchen-refrigerator for use of families of ordinary size. The ice-compartment is located in the middle division. The depth should not be more than 3 ft nor less than 2 ft, and the height may vary from 4 ft 6 in to 7 ft. The length of the front largely determines the capacity and should range from about 4 to 7 ft Fig. 1 shows, also, a most satisfactory method of accomplishing the outside-icing feature which consists of a double outside icing-door complete, with frame and jamb. This is provided by the refrigerator-builder to fit the rough opening furnished by the owner in the outside wall of the building. With this method a minimum outside opening is required to furnish a maximum inside opening for ice. The DRAIN-PIPES should be as short and straight as possible and should be readily detachable for cleansing purposes. The drain should be properly trapped in the floor of the refrigerator and carried through the floor of the building, discharging over the plumber's open connection as shown in the elevation of Fig. 1.

Fig. 2 shows a refrigerator for use in a butler's pantry where economy of space is important. The ice-compartment is of galvanized steel throughout

* Valuable data and the drawings relating to this subject were furnished the author and editor by The Jewett Refrigerator Company, Buffalo, N. Y. Practical data were furnished, also, by The Brunswick-Balke-Collender Company, New York City. There are numerous other reliable firms whose refrigerator-work has the highest reputation.

and is removable for convenience in filling as it slides on roller-bearing runways. When the ice-compartment is replaced in position the outside door closes over it. The adjoining storage-compartment is generally fitted with one removable shelf, below which is a bottle-rack for horizontally placed bottles and a space for standing bottles. The depth should be about 2 ft and the height 2 ft 8 in, under counter-top. The length of the front determines the capacity, but it should never be less than 3 ft. For a double refrigerator with a central ice-compartment and storage-compartments at either side, 5 ft is a convenient length. The exterior finish and hardware should correspond

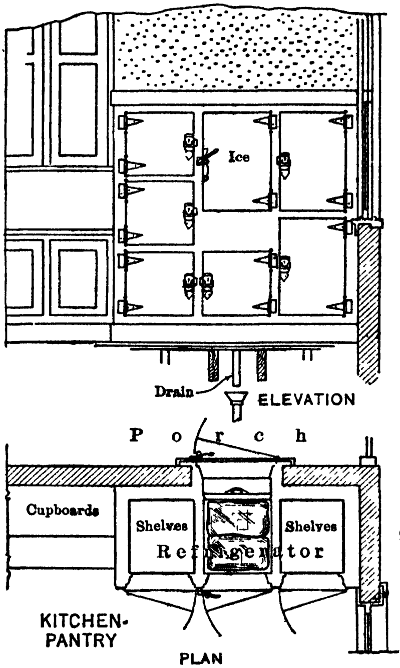

Fig. 1.* Kitchen-refrigerator for Small Family

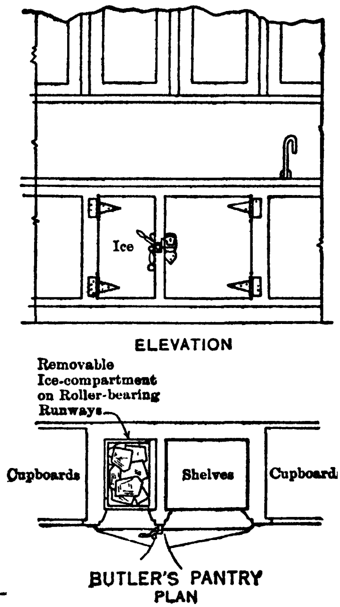

Fig. 2.* Refrigerator for Butler's Pantry

with the adjacent trim. The most sanitary and attractive interior finish for storage-compartments consists of white plate glass for the walls and ceilings and tile for the flooring. The usual complement of refrigerators for use in ordinary families consists of one adjacent to the kitchen and one in the butler's pantry. For large families the number could be the same with the capacity greater.

Refrigerators for Hotels, Clubs, Etc. MECHANICAL REFRIGERATION has largely superseded ICE as a cooling-agent where the refrigerator-equipment

* The Jewett Refrigerator Company

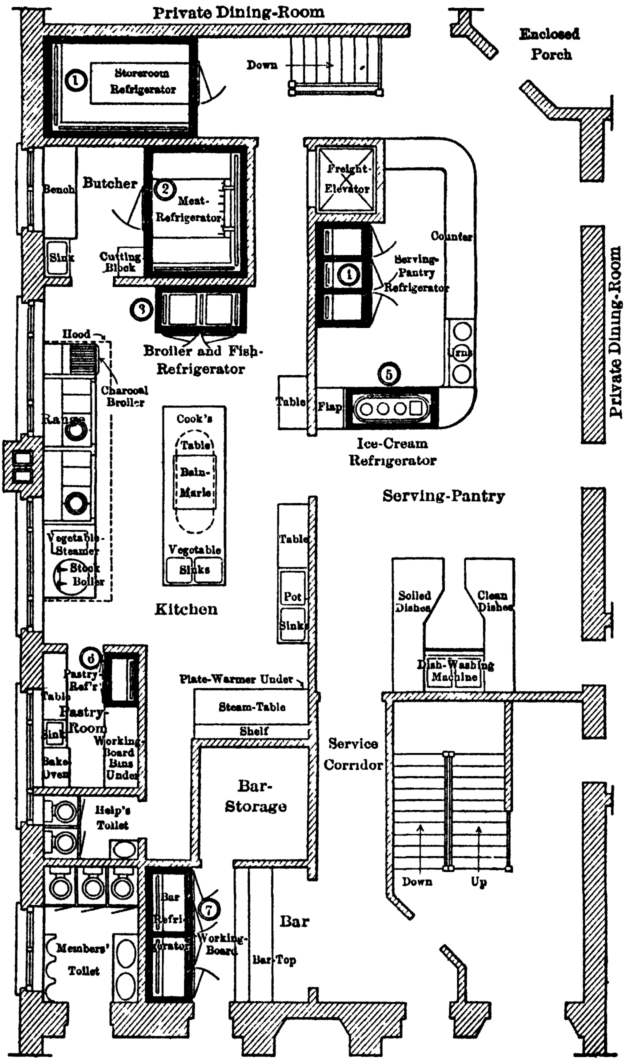

Fig. 3.* Plan of Refrigerators for Large Club-house

* The Jewett Refrigerator Company.

consists of several units, as in hotels, clubs and institutions. (See, also, Mechanical Refrigeration.) The arrangement of refrigerators is similar to that employed where ice is used, as the refrigerating-coils are often contained in compartments corresponding to ice-compartments; the alternative method is to place the coils against walls of storage-compartments. Refrigerating-coils are generally of $1\frac{1}{4}$-in pipe, the length of coil depending upon the temperature required. Fig. 3 shows a practical layout for the working-department of a good-sized club, and illustrates the proper complement of mechanically cooled refrigerators, together with adjacent operating-equipment. No. 1, a storeroom refrigerator, has the front arranged in one full-height door and is fitted with three tiers of shelves throughout. No. 2, a meat-refrigerator, is also accessible through a full-height door and is fitted with shelves and meat-racks. No. 3, a broiler and fish-refrigerator, has the front arranged in two doors, each door opening onto a series of six galvanized sheet-steel pans sliding on self-sustaining roller-bearing runways. No. 4, a serving-pantry refrigerator, is subdivided by an insulated partition into three separate and distinct compartments, those at the left and right being each accessible through two doors, while the middle compartment is accessible through one door, below which is a series of four drawers sliding on self-sustaining roller-bearing runways. The doors open onto removable shelves throughout. No. 5, an ice-cream refrigerator, occupies a position in the serving-pantry counter and has the top arranged in one lift-off cover. Its interior fittings consist of three 20-quart porcelain-lined ice-cream jars and one glacé-frame for fancy forms of ice-cream. No. 6, a pastry-refrigerator, has the front arranged in four doors, two upper doors opening onto removable shelving, and two lower doors onto pastry-pans sliding on angle-iron runways. No. 7, a bar-refrigerator, is subdivided by an insulated partition into two separate and

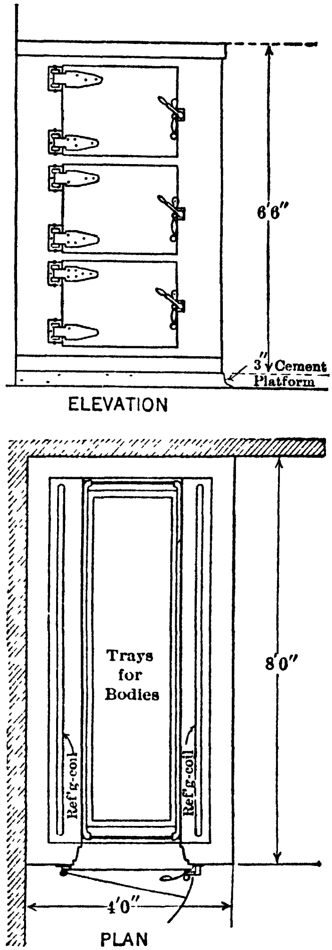

Fig. 4.* Mortuary-refrigerator

* The Jewett Refrigerator Company.

distinct compartments, each accessible through four doors. The upper doors open onto three tiers of removable shelves for standing bottles, while the lower doors open onto five tiers of racks arranged specially for horizontal bottles. The equipment described above will also satisfactorily cover the requirements of a moderate-sized hotel.

Refrigerators for Hospitals. The usual complement of refrigerators for small hospitals consists of one large storage-refrigerator, one refrigerator for the chef's use in or near the kitchen, one for milk and butter and one iron-lined chest for broken ice. For large hospitals the same number with increased capacity and with the addition of small diet-kitchen refrigerators, and possibly a mortuary-refrigerator for two or three bodies, will meet the requirements.

The Height of Large Refrigerators for hotels, clubs and institutions, to be entered through full-height doors, should be from 10 to 12 ft, if equipped with overhead ice or coil-compartments; with side ice-compartments or coils placed against walls, the height should be 7 ft 6 in or 8 ft. The smaller refrigerators, accessible through half-height doors, hinged covers, drawers, etc., should be placed on a 3-in sanitary cement platform finished with cove to floor of building. These refrigerators should not be higher than 6 ft 6 in unless provided with overhead ice or coil-compartments, in which case the height should be from 8 to 9 ft.

Insulation. (See, also, The Value of Good Insulation.) Refrigerators in modern hotels, clubs, institutions, etc., are insulated with Government-standard corkboard, the large refrigerators being constructed of 4-in cork throughout, in two courses of 2 in thickness, and with all joints broken. Cork is applied to adjacent walls of a building with Portland cement, ½ in thick, and this cement is used, also, in applying the inner course of cork to the outer course in walls, partitions and ceilings. Sometimes asphaltum, ⅛ in thick, is used instead of cement. All cork in the flooring is asphalted water-tight. Interior finish may be of Portland cement throughout or of galvanized sheets on walls and ceilings and of Portland cement on floors. Or the walls and ceilings may be of fused-on porcelain or white plate glass, and the floors of tile, all depending upon the grade and character of the building to be equipped. The insulation of smaller refrigerators consists of (1) an exterior course of ⅞-in tongued and grooved lumber, (2) two courses of water-proof insulating-paper and (3) a 3-in thickness of sheet cork in two 1½-in courses, all joints being broken. To this insulation is applied the interior lining.

Mortuary-Refrigerators. Mortuary-refrigerators should be cooled by mechanical refrigeration, the coils being placed longitudinally on both sides of the mortuary-trays. Fig. 4 illustrates a mortuary-refrigerator for three bodies. This may be used as a unit in designing mortuary-refrigerators of larger capacity, or the height may be reduced to 5 ft and the bodies placed in two instead of three horizontal tiers. Mortuary-refrigerators sometimes have both fronts finished and equipped with doors so that bodies are accessible for identification or examination from both fronts.

RECOMMENDATIONS FOR CONSTRUCTION OF COOLING ROOMS AND LARGE REFRIGERATORS *

Definitions. Refrigerator. The term REFRIGERATOR shall apply to any portable refrigerator of the reach-in or service type, built either set-up or sectional.

Cooling-Room. A walk-in refrigerator of portable, sectional construction shall be known as a COOLING-ROOM.

Cold-Storage Room. The term COLD-STORAGE ROOM shall apply to any refrigerator of the built-in type, i.e., built of cement and cork or other insulation material direct to one or more building walls.

Bunker. The space arranged to receive the cooling coils or mechanical equipment shall be known as the BUNKER.

Coil Deck. The term COIL DECK shall apply to the arrangement directly below the cooling coils or other refrigerating equipment to catch the drip from the same.

Drain-Trough. The arrangement along the lower edge of the coil deck to prevent the water from dripping into the storage compartment shall be known as the DRAIN-TROUGH.

Baffle. The term BAFFLE shall apply to the vertical partition separating the warm air duct from the coil space.

Cold-Air Duct. The space through which the cold air descends from the bunker to the storage compartment shall be known as the COLD-AIR DUCT.

Warm-Air Duct. The space through which the warmer air ascends from the storage space to the bunker shall be known as the WARM-AIR DUCT.

Bunker Door. The door provided to allow placing of, or access to, the coils in the bunker shall be known as the BUNKER DOOR.

The following are considered standard sizes for cooling-rooms, the first dimension being the length and the second the depth. The standard height of the sizes is approximately 9 ft 10 in.

7′ 0″ × 5′ 0″	8′ 0″ × 8′ 0″	10′ 0″ × 8′ 0″
8′ 0″ × 6′ 0″	9′ 0″ × 7′ 0″	12′ 0″ × 10′ 0″

When the height of a cooling-room is referred to as 10 ft it may be actually only 9 ft 10 in high over all measured on the body of the room in order that it may be used in a room with a 10-ft ceiling.

Specifications. 1. A grade "A" refrigerator or cooling room is one wherein the structural details and insulation shall be such that over years of service the loss of refrigeration through the walls shall not exceed 3 Btu per sq ft of outside area, per degree difference per 24 hours.

2. The entire upper section of the refrigerator or cooling-room should be devoted to bunker space.

3. The coil decks should be constructed with supports of sufficient structural strength to carry the weight of the cooling coils of refrigerating equipment placed above them, or instead proper supports should be placed above the deck so that coils may be suspended from same by hangers provided as part

* Prepared by the Joint Commercial Refrigeration Committee of the Refrigerating Machinery Association and Commercial Refrigerator Manufacturers.

of the coil equipment. The overhead supports for the coils should be secured to the wall framing and should in no way be fastened to the top or ceiling of the refrigerator.

4. The coil deck should pitch toward the cold-air duct sufficiently to create drainage and provide proper circulation.

5. With cooling-rooms up to and including 8 ft 0 in wide outside and across the decks, a single deck shall be deemed sufficient, with the warm-air duct along one side and the cold-air duct along the opposite side.

6. Cooling rooms over 8 ft 0 in wide outside and across the decks shall have a deck on each side pitched toward the cold-air duct with the warm-air duct opposite the cold-air duct.

7. The baffle forming the warm-air duct should be stopped at a distance from the ceiling equal to the width of the warm-air duct.

8. Cold and warm-air ducts should extend the full length of the cooling-room, and both baffle and deck should touch the end walls.

9. Minimum height between the deck and ceiling of the cooling-room should be 27 in in rooms 10 ft 0 in high and other height rooms in proportion.

10. The coil decks shall be constructed and provided with approved insulation so as to have a heat transmission not exceeding 5 Btu per sq ft, per degree difference each 24 hours.

11. The baffles shall be constructed and insulated so as to have a heat-transmission not to exceed 7.4 Btu per sq ft, per degree difference.

12. The top of the coil deck and inside of the baffle shall be covered with some form of rust-resisting metal.

13. The bunker door should be placed as near as practical in the center of one end of the bunker.

14. Bunker doors shall be at least 2 in higher than the height of the baffle and shall have a minimum width of 27 in. The minimum height of the bunker or coil door in rooms 9 ft up to and including 11 ft in height should be 23 in in the clear. In rooms over 11 ft high the doors should have a minimum height in the clear of 36 in. The heights specified give the measurement of the necessary unobstructed opening.

15. If wedge strips are used on top of the deck for supporting the coils or cooling equipment, they shall be level on top and not less than 2 in high at the low point of the wedge or high point of the deck and higher if possible; such wedge strips should also be notched at the lower end so that they will properly clear the drain-trough and offer no obstruction to the flow of drainage therein.

16. There should be at least 6 in clear space between the baffle and the coils, congealing tanks or tubes, and there should be at least 4 in clear space horizontally between the nearest edge of the cold air duct and these parts of the equipment. Supports for such parts should be arranged so that there will be at least 6 in clearance between their lowest edge and the highest point of the deck.

17. Wherever it is necessary to carry cold pipes through the walls of cooling rooms or refrigerators, the pipe insulation should be carried 1 in inside the cooling-rooms or refrigerator. These openings should be sealed air-tight with a water-proof, odorless sealer inside and outside.

18. Cold pipes should not run through or across warm-air ducts unless it is absolutely necessary. In the event that it is necessary to do so the pipe should be thoroughly insulated or provided with drip troughs to carry the drippage from them to the bunker deck. Cold pipes should not be run through the food compartments unless absolutely necessary. When necessary to do so the pipes should be thoroughly insulated unless their location

is such that proper drip-troughs can be provided to prevent the drippage to the floor or on the produce stored.

19. Wherever cold pipes run through or across cold-air ducts, they should either be well insulated or drip-pans provided to catch the drippings and carry same to the bunker deck.

20. In no case should any pipe be so located as to interfere with the free circulation of air through both the warm and cold-air ducts. In no event should pipes of any kind be run horizontally in either warm-air or cold-air ducts.

21. Pipes that will frost or sweat should not pass through the floor of cooling rooms. If this cannot be avoided, the pipes should then be well insulated not only where they pass through the floor but to the point where they come out to the open below the floor so that frost or moisture may not be permitted to collect between the room-floor and building-floors or foundations. Where pipes pass through floors, there should be flashing extending at least 2 in above the floor sealed water-tight to the covering and the cooling-room floor.

MECHANICAL REFRIGERATION *

A Brief Description of Methods in Common Use for Producing and Applying Refrigeration, with Special Reference to Small Plants

A British Thermal Unit (Btu) is the quantity of heat required to raise the temperature of 1 lb of water 1° F. Heat used in this way, that is, to raise the temperature of water or other substance, is said to be present in that substance as SENSIBLE HEAT, or, in other words, heat, the presence of which we can feel, or sense.

The Heat of Liquefaction, or so-called LATENT HEAT OF LIQUEFACTION of a mass of ice, is the amount of heat it will absorb in melting. One pound of ice at 32° F. will absorb 144 Btu in melting to water at 32° F. Heat coming into a cake of ice is thus absorbed in melting the ice and becomes what is known as LATENT HEAT, or heat absorbed without any rise in temperature. If the ice is at a lower temperature than 32° F., or if the water resulting from the melting rises above 32° F., additional heat will be absorbed as SENSIBLE HEAT.

The Specific Heat of a substance is the ratio of the quantity of heat required to raise the temperature of a certain weight of the substance one degree to that required to raise the same weight of water from 62° to 63° F.

The Heat of Vaporization of water or of any other liquid is the amount of heat it will absorb in vaporizing, in evaporating from a liquid to a gas, or will give out in returning from the gaseous to the liquid state.

Transfer of Heat occurs in three ways: (1) by convection, (2) by radiation and (3) by conduction. For instance, if particles of air in a refrigerator adjacent to a source of heat become warmed they circulate and distribute the heat by CONVECTION through the refrigerator-box. Heat will pass from a warm substance, as from the filament of an incandescent lamp, out into the box by RADIATION. Heat will enter the box through the walls by CONDUCTION.

Heat-Transmission. When the temperatures on opposite sides of any surface, as for instance, a wall, are unequal, heat will pass by conduction through the material from the warmer to the cooler side. The rate of this movement is the RATE OF HEAT-TRANSMISSION and is stated in terms of the quantity of

* Compiled and adapted, by permission, from data included in a paper by R. F. Massa See, also, Refrigerators.

heat (called Btu) which will pass through 1 sq ft of surface in 24 hours, per degree temperature-difference between the two sides of the wall.

Some Advantages Claimed for Mechanical Refrigeration.

(1) Lower temperatures can be obtained with refrigerating-machines than with ice.
(2) The inconvenience of handling ice is avoided.
(3) There is no accumulation of slime in the refrigerators as from the melting of even the best ice.
(4) Refrigerators cooled mechanically are dryer than ice-cooled boxes because the moisture is frozen out of the air and deposited on the cooling surfaces.
(5) There is generally a better air-circulation, resulting in a more uniform temperature and dryer atmosphere throughout the compartment.
(6) With proper design of refrigerator and refrigerating-machine any desired temperature can be obtained.
(7) Refrigeration produced mechanically is often cheaper than refrigeration produced by melting ice.

Operation of Refrigerating-Machines. In almost all methods of producing cold, advantage is taken of the fact that when a liquid evaporates it usually cools both itself and its surroundings, and changes into a gas or vapor. There are several liquids which are easily made to evaporate and produce this cooling effect, and, were it not for their cost, refrigeration could be very simply produced by supplying a steady stream of the liquid and allowing the vapor or gas evaporated to escape into the atmosphere. A refrigerating-machine is practically an apparatus for saving this gas which has evaporated and returning it to its liquid form to be used over again. In this process of recovery and condensation the gas gives out the heat which it has previously absorbed in evaporating This heat is carried away by flowing water, which, in absorbing the heat, rises in temperature.

Types of Refrigerating-Machines. In the (1) COMPRESSION-TYPE of refrigerating-machines the recovery of the gas is effected by drawing it away from the point where it has been evaporated and pumping it under increased pressure into a chamber where it gives out its heat to the water-cooled walls of the chamber and returns to the liquid state ready to be used over again. In the (2) ABSORPTION-TYPE of refrigerating-machines ammonia is generally used and the recovery of the gas is effected by bringing it into contact with water with which it unites chemically. The solution thus formed is pumped into another chamber, and heat is applied to drive off the ammonia-gas which is then condensed under high pressure. It is now ready to be reevaporated and reproduce its cooling effect. In all cases of large units, and in all cases of either large or small units where exhaust-steam is available in sufficient quantities, absorption refrigerating-machines are very economical.

Liquids Used in Refrigerating-Machines. A number of liquids have been used in refrigerating-machines, the ones commonly employed being (1) AMMONIA, (2) CARBON DIOXIDE and (3) SULPHUR DIOXIDE. Various practical considerations determine which is to be used in any particular design of machine. With (1) AMMONIA the advantage is the lower working pressures, from 15 to 200 lb per sq in, which are easy to deal with. An advantage over carbon dioxide is that leaks are very easily located Ammonia-fumes, however, are offensive and sometimes dangerous in case of a break. With (2) CARBON DIOXIDE the advantage is in its inoffensive odor Its disadvantages

are the high pressure at which it works, from 300 to 1 200 lb per sq in, the relative difficulty of holding these pressures and of finding small leaks, owing to its slight odor and chemical inactivity. With (3) SULPHUR DIOXIDE the advantage is its comparatively low working pressure, which is not above 75 lb per sq in. Its great disadvantage is that with moisture it forms an acid which rapidly corrodes the apparatus. At one time this disadvantage was fatal, since with the old-type machines, air and moisture were constantly being drawn into the system more or less rapidly and mixed with the sulphur dioxide. This difficulty has been overcome in modern types of machines in which the refrigerant is hermetically sealed in the machine and chemical action, therefore, prevented.

Rating of Refrigerating-Machines. A 1-TON REFRIGERATING-MACHINE is a machine which, if operated for 24 hours, will absorb the amount of heat which 1 ton of ice would absorb in melting. If the machine is operated a shorter time per day, a less amount of heat will of course be absorbed, and in order to maintain the temperature during the period when the machine is not running, some means must be adopted for storing cold. (See paragraph below.) Refrigerating-machines are sometimes rated in terms of ICE-MAKING CAPACITY, that is, in terms of the amount of ice the machine will make in 24 hours. This is always less than the refrigerating capacity because some refrigerating effect is required to cool the water down to 32° F. before the freezing can begin, and the ice is usually cooled several degrees below 32° F., which requires a still greater capacity. There is also some flow of heat into the apparatus. These elements vary considerably so that from some points of view ICE-MAKING CAPACITY might be considered an unsatisfactory method of rating some refrigerating-machines.

Applying the Cold. According to one classification there are three common systems of applying the cold. These are, (1) the DIRECT-EXPANSION SYSTEM (2) the BRINE-SYSTEM and (3) the COLD-AIR SYSTEM.

(1) In the DIRECT-EXPANSION SYSTEM the refrigerant is evaporated in coils of pipe placed directly in the room to be cooled

(2) In the BRINE-SYSTEM the refrigerant is used to cool brine, which is then circulated through coils of pipe in the room to be cooled.

(3) In the COLD-AIR SYSTEM a current of air is chilled by passing it over coils of pipe cooled directly by the evaporating refrigerant, or by brine, or by passing it through a spray of cold brine; and this chilled air is then passed into the room and circulated back to the cooling-coils, the whole operation being repeated indefinitely.

All of these systems have their advantages and disadvantages. While the brine-system is a little more expensive to operate in large plants, the temperature is more easily controlled than with the direct-expansion system, and in practice in small plants it is found as economical in operation in spite of its theoretical disadvantage. Furthermore, in case of any breakdown in the machine, the temperature can be held for a time by circulating the brine until it becomes too warm to be of use, whereas with direct expansion the temperature will begin to rise immediately upon the stopping of the machine. The cold-air system is not as applicable where any drying of the goods stored would be harmful and there is some risk of carrying fire in the air-passages. It is much used, nevertheless, for such service as chocolate-dipping rooms, ice-cream hardening, fur-storages, etc.

Storage of Cold. When temperatures are to be maintained while the refrigerating-machine is shut down, COLD must be STORED. In the brine-system

this is effected by cooling a comparatively large body of brine which warms slowly as it is circulated. Where the brine-circulating pump as well as the machine must be stopped, so-called PRESSURE-TANKS may be placed in the piping-system in the room being cooled; the mass of brine in these tanks absorbs the heat and helps to maintain an approximately even temperature. Where the direct-expansion system is used, a part of the cooling-coils may be immersed in a tank of brine placed in the room and the remainder of the coils arranged for the direct cooling of the room. In some places the spaces available will not permit the use of brine-storage tanks. In cases of this kind smaller tanks may be used and filled with water, or a weak brine which will freeze at a temperature a little below 32° F. Since 1 lb of ice in melting will absorb 144 Btu and 1 lb of brine rising in temperature, say 20°, will absorb only from 14 to 16 Btu, the saving of space is apparent. It must be absolutely certain that the refrigerant reaches the tank first at the bottom and that the air to be cooled reaches it first at the top so that the ice in forming shall not bulge or burst the tank. If the congealing mass were to freeze from the top down the tank would be strained and finally leak, because of the expansion of the ice in freezing. Another fact to be considered is that where water, only, is frozen, a resulting high temperature may be obtained in the refrigerator, since the brine must be warmer than the ice in order to melt it, and the refrigerator just that much warmer, or warmer than an ice-cooled box. In calculating the proper sizes of tanks for storing brine, it should be remembered that, usually, the period during which the machine is shut down coincides with the period during which the demand for refrigeration in the box is the least. The amount of heat to be absorbed is usually only that entering through the insulation, as the doors are shut and no food is put in or removed.

Description of Refrigerating-Machines. As explained in the preceding paragraphs refrigerating-machines may be divided generally into two classes, (1) the COMPRESSION-TYPE and (2) the ABSORPTION-TYPE.

(1) The Compression-Type of Refrigerating-Machines may be subdivided as follows:

(*a*) The open type of machine, which is made both vertical and horizontal, and both single and double-acting, that is, compressing the gas at one end or at both ends of the cylinder. (*b*) The partially enclosed type of machine, in which all the moving parts of the compressor proper are enclosed within the frame of the compressor, except the fly-wheel and the main shaft which enters the frame of the machine through a stuffing-box. Such valves, also, as are required in the system are exposed. (*c*) The wholly enclosed type of machine, in which all of the working parts are enclosed in a hermetically sealed container.

(*a*) One advantage of the open type of machine is that any lack of adjustment due to wear can be readily corrected; so that, with proper attention, it gives excellent results. For large installations this is considered by many to be a most efficient type of machine.

(*b*) The enclosed type of machine resulted from the effort to reduce the amount of attention required by the open machine, to cheapen its construction and to reduce the possibility of trouble from inexpert tampering. An objection to machines of this type is that when adjustments have to be made the working parts are relatively inaccessible.

(*c*) With the wholly enclosed type of machine it is claimed that the loss of the refrigerant is prevented by the hermetical sealing of the apparatus, and that the working parts, being completely enclosed, are protected from deterioration due to outside causes or tampering.

(2) **The Absorption-Type of Refrigerating-Machines** are of two kinds, differing principally in the proportioning of the parts. In the one machine high-pressure steam is used; in the other the proportions are such that low-pressure or exhaust-steam may be used. Where exhaust-steam is available machines of this type are found to be very economical, and this is true, also, for all large units whether or not exhaust-steam is used. Full descriptions of these machines with detailed plans and layouts may be obtained from the various manufacturers.

Calculations for the Capacity of a Refrigerating-Machine. Heat enters the refrigerated compartments, (1) through the walls, (2) with warm goods, (3) by the interchange of the outside air when doors are opened and by air-leaks, since the cooled air is the heavier and immediately flows out when a door is opened, (4) from lights or from the heat of the bodies of workers, and (5) from any change of state occurring in the goods, such as freezing, fermenting, etc. In large rooms these various sources of heat should be analyzed separately. In small refrigerators, as in hotels, kitchens, dwellings, etc., a rough rule, quite as accurate as a more elaborate analysis, allows a certain number of Btu per cubic feet of refrigerated space per 24 hours. This amount varies with the character and location of the box, the nature of its insulation, the temperatures desired and so on. It will be seen that the insulation, while of great importance, is not by any means the only important factor in this class of boxes. For domestic refrigerators in which a temperature of from 35 to 50° F. is maintained, 300 Btu per cu ft of refrigerator per 24 hours should be allowed. For boxes in hotel or restaurant-kitchens, 600 Btu, or even 900 Btu in extreme cases and where low temperatures are required, should be allowed. For butchers' coolers or large storage-boxes in hotels, etc., from 200 to 250 Btu per cu ft per 24 hours should be allowed. A check on the above figures for the large type of box is the following: * "When the exact conditions under which cold-storage rooms are to be operated are known, namely, the size and shape of the rooms, the quality of the insulation, the kind and quantity of goods to be handled per day and the temperatures at which they are received and at which they are to be held, the amount of refrigeration required can be estimated very closely by the following rule: (1) Calculate the exact area of exposed surface in the walls, floor and ceiling of the room in square feet, multiply the total number of square feet by the number given in the table for the required temperature and divide the product by 288 000. (2) Multiply the amount of goods, in pounds, to be stored per day by the number of degrees of heat to be extracted by the specific heat of the goods, and divide by 288 000. This will give the amount of refrigeration, in tons per day, necessary to maintain the temperature required for the goods. (3) Add these two amounts together. The total will be the amount of refrigeration, in tons per day, required to maintain the temperature required for the goods and for the room. (4) If the goods are to be frozen, the latent heat of freezing should be added to the number of Btu to be extracted."

With small machines it is necessary to allow a greater capacity of machine for a given size of box than with large machines, since, with the latter, one can always throw a large part of the machine-capacity to any given box where special need may exist; whereas to do this with the small machine would almost certainly rob some other box, if indeed there happened to be another box. It is never possible to determine with mathematical certainty exactly how much refrigeration is required for a given case. It is best to allow for this fact and to be sure the machine is amply large. Where an existing ice-cooled box is to

* **Taken from Levey's Refrigeration Memoranda.**

be cooled mechanically one check upon the size of the machine required is the amount of ice used. This check is more apt than any other, however, to lead to erroneous conclusions unless the figures are properly analyzed.

For rooms containing less than 1 000 cu ft			
If maintained at	0° F.	multiply the exposed surface by	1 775
If maintained at	5° F.	multiply the exposed surface by	710
If maintained at	10° F.	multiply the exposed surface by	535
If maintained at	20° F.	multiply the exposed surface by	355
If maintained at	32° F.	multiply the exposed surface by	265
If maintained at	36° F	multiply the exposed surface by	180
For rooms containing from 1 000 to 10 000 cu ft			
If maintained at	0° F	multiply the exposed surface by	1 250
If maintained at	5° F.	multiply the exposed surface by	600
If maintained at	10° F	multiply the exposed surface by	300
If maintained at	20° F	multiply the exposed surface by	190
If maintained at	32° F	multiply the exposed surface by	160
If maintained at	36° F.	multiply the exposed surface by	125
For rooms containing more than 10 000 cu ft			
If maintained at	0° F	multiply the exposed surface by	1 100
If maintained at	5° F.	multiply the exposed surface by	550
If maintained at	10° F	multiply the exposed surface by	275
If maintained at	20° F.	multiply the exposed surface by	180
If maintained at	32° F.	multiply the exposed surface by	140
If maintained at	36° F	multiply the exposed surface by	110

Another Method of Determining the Capacity of a Refrigerating-Machine. The following is a method that gives good results, except that allowance may be made in the larger boxes and where brine-storage tanks are provided in the box for the steadying effect of the mass of cold brine:

(1) The ice-consumption for the hottest month of the year should be determined. This will give the average ice-consumption for that month.

(2) The average temperature that is maintained in the box with ice should then be accurately determined. This will usually be from 55 to 65° F. It will commonly be stated to be anywhere from 40 to 45° F., but these temperatures are seldom obtained. Even if they are, with a full ice-chamber and the box closed for long periods the average will be above these figures. Unless, therefore, there is positive assurance to the contrary, from 55 to 60° F. should be considered the average temperatures.

(3) A calculation should then be made of the heat-inflow through the insulation, with a temperature of 55° F. in the box and with the average summer temperature outside. The difference between the heat-inflow through the insulation and the total heat actually absorbed by the melting of the ice is the amount entering the box from other sources than through the insulation. This access of heat ordinarily occurs during the hours of daytime only, that is, when the box is being opened, since at night the box will remain closed. A machine of sufficient capacity to produce the temperature actually obtained with ice must, therefore, be of larger rated capacity than that indicated by the actual ice-consumption; and how much larger it should be can be determined by this method.

(4) A further fact which it is claimed should be taken into account in deter-

mining the proper size of a machine is that temperatures obtainable with ice are often unsatisfactory. If they were always satisfactory, one reason for putting in cooling-machinery would be done away with. Where 55° F. is obtained with ice, from 35 to 45° F. will be required with mechanical cooling and the machine-size must be further increased in the ratio of the temperature-differences between average summer temperatures and 35° F., and average summer temperatures and 55° F.

(5) The cooling-machine if installed in accordance with these figures would handle average-weather conditions but would not be adequate for extreme hot-weather conditions, the most important conditions to be met by cooling-machinery. It is necessary, therefore, to further increase the size of the machine in the ratio of the difference in temperature between maximum summer temperature and 35° F., and average summer temperature and 35° F.

(6) A further allowance should be considered, namely, the fact that in many cases, for one reason or another, it is not possible, or else not desirable, to operate the machine except during certain periods of the day, and the machine-size must be increased as much as may be required to take care of these conditions.

(7) If the machine is not placed directly at the box to be cooled, allowance must be made for the heat-inflow into the insulated brine-mains. The amount of heat entering from this source is often of considerable importance, particularly with small machines. The table below gives heat transmissions for cork pipe-covering and some other materials.

Water and Milk-Cooling. Mechanical refrigeration as applied to cooling water and milk differs in one respect from other classes of refrigerating-work. A relatively intense quantity of cooling effect is called for in a brief interval of time. For instance, in a drinking-water system the heaviest requirements may come at the noon-hour. In a bakery, also, the demand for chilled water will be intermittent, a large quantity of water being required for the dough-mixing. In dairy-work the milk must be cooled very rapidly to check the development of bacteria which grow with incredible rapidity within the temperature-range of from 110 to 50° F. To install a large enough refrigerating-machine to produce the required cooling effect as it is needed would in most cases call for a very large machine. This is overcome by using a smaller machine and allowing it to operate for a longer time, say throughout the day, storing the refrigerating effect produced by cooling a large body of brine, or melting the ice as rapidly as may be required. For instance, if 50 cans of milk, of 40 qts each, are to be cooled from a temperature of from, say, 75 to 35° F., in 1 hour, the refrigeration required will be 50 cans times 40 qts times 2 lb per qt times (75° F. — 35° F.), which equals 320 000 Btu. Milk is treated in the calculation as having the same specific heat as water, since water forms so large a percentage of its total weight. This amount of refrigeration produced by a machine running 12 hours per day would require the machine to absorb 320 000 Btu divided by 12, or 26 000 Btu per hour. The quantity of brine necessary to store the cooling effect may be calculated closely enough for practical purposes by using the following approximate figures. The specific heat of brine is 0.75. The weight of the brine is 9 lb per gallon. The permissible temperature-range of the brine depends upon the conditions and may be from, say, 30 to 15° F., or lower. In other words, the temperature to which the brine can be permitted to rise is limited to the temperature it must produce in the room or in the subtsance being cooled, and the temperature to which the brine can be cooled in storing cold is limited by the decrease in economy of the refrigerating-machine at the low temperatures.

The Value of Good Insulation. The importance of good insulation cannot be too strongly emphasized. A cold-storage room or refrigerator and its contents may be cooled by ice or mechanical means, but unless the walls are adequately insulated, the demand caused by the inflow of heat through the poor insulation may be more than the ice-supply or refrigerating-machine can meet to maintain the required temperature. The almost universal standard of insulation for cold-storage rooms is a 4-in thickness of pure-cork sheet. The following table shows the heat transmitted through 1 in in thickness of each of the substances, per square foot of exposed surface per degree difference in temperature per 24 hours.

Pure-cork sheets	6.4 Btu
Hair-felt	7 3 Btu
Impregnated cork boards	8 5 Btu
Rock-wool blocks	8.0 Btu
Waterproofing lith-blocks	8 5 Btu
Spruce, clear and dry	16 0 Btu
White oak	26 0 Btu

Incidental Notes on Refrigerators. **Drawers.** In restaurant-kitchens and elsewhere it is sometimes convenient to have a box fitted with a number of refrigerated drawers. The heat-leakage through the many joints, through slides which are invariably only partially closed, and through the poor insulation of the drawers, is very great. Where it is at all possible to do so, it is best to arrange an insulated door covering the entire drawer-space.

Table of Temperatures Recommended for Use in the Equipment Specified Under Normal or Average Operating Conditions *

Description of article	Location of thermometer	From degree named below	To degree named below
Small market cooling-room	Center of rear wall	38	45
Large storage cooling-room	Center of rear wall	36	42
Grocer's refrigerator	Small lower compartment	42	48
Restaurant service-refrigerator	Small lower compartment	42	48
Restaurant storage cooling-room	Center of rear wall	38	45
Florist's refrigerator		48	54
Top display case	Center of bottom	42	48
Floor display counter	Center of bottom	42	48
Floor display counter, heavy construction	Center of bottom	36	40
	Center of top shelf	44	48

* Issued by The Joint Commercial Refrigeration Committee, 422 Murray Bldg., Grand Rapids, Mich.

Anterooms. In storage-rooms of medium to large size the air-interchange due to opening doors is reduced to a minimum by arranging an anteroom or entry which, after it is entered, has its outer door closed before the door to the storage-room proper is opened. Where two rooms are side by side, it is often possible to reduce the interchange of air by treating the one room as an anteroom of the other, having but one door to the outside air.

Doors. Special note should be made as to the design of doors for refrigerated rooms or boxes. There is a common idea that a refrigerator-door should be beveled. As a matter of fact no more certain means of ensuring air-leakage could be devised. A perfectly fitted beveled door, hung accurately in place, could perhaps be made tight in the beginning. This door in service at once begins to sag, since a refrigerator-door is always heavy. It immediately becomes impossible to force it to a tight seat and continuous leakage of air begins. A refrigerator-compartment door is most readily made tight by having a flat surface on the door come up against a corresponding surface on the frame, with a soft gasket of some kind between them. There are several well-made refrigerator-doors on the market at prices low enough to make it doubtful economy to attempt the home-made article.

Approved Cold-Storage Temperatures

Articles stored	Degrees Fahrenheit
Beef	36 to 40
Lamb and mutton	32 to 36
Hogs	29 to 32
Veal	34 to 36
Meats, in pickle or brine	35 to 40
Butter, must be kept separate from other goods	0 to 38
Eggs	29 to 32
Cheese	32 to 34
Lard	38 to 40
Poultry, to freeze	5 to 10
Poultry, when frozen	25 to 28
Game, to freeze	5 to 10
Game, when frozen	25 to 28
Fish, retail fish-counters should be cooled with ice rather than mechanically	25 to 28
Oysters	33 to 45
Beer	33 to 42
Wines	40 to 45
Cider	30 to 40
Fruits	33 to 36
Vegetables	34 to 40
Canned goods	38 to 40
Flour and meal	40
Furs	25 to 32
Brine for ice-cream freezing	5 to 10
Ice-cream, air hardening	5
Ice-cream, serving-temperature	14 to 16

Arrangement of Brine-Mains. In laying out mains to carry brine from the refrigerating-machine to the refrigerator, there are a few simple points to be cared for. For the convenience of the pipe-covering man, the flow and return lines should be placed far enough apart so that he can get his covering onto each pipe without cutting it to pieces, or else they should come close together so as to be covered together. A common difficulty experienced in brine-systems of refrigeration, where the cooling-coils in several compartments are fed from the same main, is that when the adjustment of the valve controlling the flow of brine through one coil is changed, it upsets the adjustment of the whole system. This is due to too small mains or too small a pump, or both. A similar action is observed when the opening of a faucet on a water-pipe checks

the flow from other open faucets on the line. The ideal cross-section area of the brine-mains is as nearly as possible equal to the combined cross-section area of the coils which they serve at any one time. Even with this proportion, however, it is not possible to absolutely ensure that the lower coils will not rob the upper ones, or even drain them completely in some systems of piping. A most effective, even if somewhat expensive method of overcoming this difficulty, is by the addition of a third main. In this arrangement it is not possible for one coil to rob another to the point of draining it.

Calculations for the Necessary Amount of Cooling-Surfaces. No hard-and-fast rule can be given regarding the proper amount of cooling-surface for compartments of various sizes, since the design and arrangement of the cooling-surface and the freedom with which the air circulates over it greatly affect the amount required. As a general guide, however, and where the conditions are such as to permit a good circulation of the air, the following formula will give good results. It will be understoood, of course, that the refrigeration required in the given room has been determined as previously indicated. The cooling-surface required, in square feet, per ton of refrigeration equals $4\,700/(T - t)$ in which T is the temperature desired in the compartment, and t the average temperature of the brine.

TOWER-CLOCKS *

Rule for Diameter of Dials. "To look well and show plainly, dials should be 1 ft in diameter for every 10 ft of elevation and should set out flush with or close to the line of the building or tower." †

Dimensions of Some Large Clock-Faces. Colgate's Factory, Jersey City, N. J. The diameter of the dial is 40 ft. The minute-hand is 20 ft long and 2 ft 11 in in extreme width, and the hour-hand is 15 ft long and 3 ft 10 in in extreme width. The minute-hand weighs 640 lb and the hour-hand 500 lb. This is the largest clock in the world.

Bromo-Seltzer Building, Baltimore, Md. The dials are 24 ft in diameter. The minute-hand is 12 ft 7 in and the hour-hand 9 ft 8 in from tip to tip. The minute-hand weighs 175 lb, the hour-hand 145 lb.

Daniels-Fisher Building, Denver, Colo. The dials are 15 ft 6 in in diameter. The minute-hand is 7 ft 10 in and the hour-hand 5 ft 7 in long.

Maryland Casualty Building, Baltimore, Md. The dials are 17 ft in in diameter. The minute-hand is 8 ft 4 in and the hour-hand 5 ft 11 in long.

Elgin Watch Company's Factory, Elgin, Ill. The dials are 14 ft 6 in in diameter. The minute-hand is 7 ft 4 in and the hour-hand 5 ft 4 in long.

Tower-clock, Station of the Central Railroad of New Jersey, at Communipaw, N. J. The diameter of the single dial is 14 ft 3 in; the minute-hand is 7 ft long and weighs 40 lb; the hour-hand is 5 ft long and weighs 28 lb. The motive power is furnished by a weight of 700 lb, hung from a 3/8-in steel cable.

Four-dial clock, Produce Exchange Building, New York. The diameter of each dial is 12 ft 6 in.

Four-dial clock, Chronicle Tower, ‡ San Francisco, Cal. The diameter of each dial is 16 ft 6 in; length of minute-hands, 8 ft; length of hour-hands, 5 ft 6 in. The mechanism of the clock is 6 ft 1 in high and weighs 3 000 lb.

* For a description of the requirements of installation of tower-clocks, see page 154 of "Churches and Chapels," by F. E. Kidder.

† Seth Thomas Clock Company, Thomaston, Conn.

‡ Destroyed in the earthquake and fire.

Pneumatic clock, City Hall and Court-House, Minneapolis, Minn. The dials are 23 ft 4 in in diameter.

Four-dial clock, City Hall, Philadelphia, Pa. The diameter of each dial is 26 ft.

LIBRARY BOOK-STACKS

The Stack-Work in General. The stack-room of a library is usually cut off by fire-proof doors from the rest of the building. The customary practice among architects is to make the stack-work a separate contract and have the general contractor turn the stack-room over to the stack-contractor with finished floors, walls and ceilings. The stacks, made entirely of incombustible materials, are then built as an independent structure.

Book-Ranges. The book-ranges are usually double-faced and are placed in parallel rows with aisles between. The minimum aisle-width is about 2 ft 4 in. Radial ranges waste space and are costly. Single-faced ranges are relatively more expensive than double-faced ranges.

Tiers. All stacks are divided in their height into tiers by deck-floors in order that all shelves may be easily reached. The regular tier-height is 7 ft or 7 ft 6 in.

Deck-Floors. Deck-floors are composed of slabs of ¾-in rough plate glass or 1¼-in white marble, supported on steel framework A long, narrow opening or deck-slit is left between the edge of each deck-floor and the face of each range to allow proper ventilation of the stack-tiers. The net thickness from top of deck to bottom of steel framework is from 3¼ to 3¾ in for ordinary spans. The deck-floors are carried by the shelf-supports.

Vertical Communication. Continuous flights of stairs of simple design and construction are placed at central points. Books are moved up and down by means of dumb-waiters operated by hand, for short runs, or by electric power controlled by push-buttons.

Shelf-Supports. The shelf-supports are made in various ways, differing with each manufacturer. In the best construction they extend the full width of the shelves so as to hold up the shelves and books without the use of any projecting brackets. They are made of sufficient strength to carry the combined loads of books, deck-floors and superimposed stack-piers. They should provide for a uniform shelf-adjustment at intervals of about 1 in. Compactness is important. Open-work shelf-supports promote proper lighting and ventilation.

Shelves. In each tier of regular height there are usually six rows of adjustable shelves and one row of fixed shelves. Shelves are generally 8 or 10 in wide and 3 ft long. Other sizes are supplied if necessary. The adjustable shelves are made of solid plates of sheet steel or of parallel bars with spaces between. The fixed shelves are placed about 2 in above each floor-level. They are made of solid plates of steel to form dust-stops, fire-stops and water-stops between the tiers.

Finish. The adjustable shelves are always completely finished with baked enamel before delivery. The fixed parts, also, of the stack-construction may be finished at the shop with baked enamel, or preferably with air-drying enamel, after erection at the building, so as to permit repair.

Lighting. Electric-light wires are carried in metal conduits supported by the steel framework of the deck-floors. Lights of 16 candle-power are spaced about 6 ft apart in range-aisles and 12 ft apart in main aisles.

Heating. Indirect radiation is best for books. The lower tiers, only, of a stack should be heated, to prevent the upper tiers from becoming too warm.

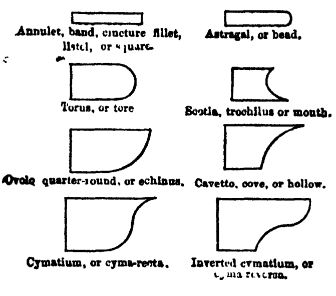
Ventilation. Large stacks are usually ventilated artificially to prevent the entry of dust and outside air through open windows. In the Library of Congress, in Washington, D. C., fresh, filtered and tempered air is forced in at the bottom tier, finds its way up through the stack by means of the deck-slits and is drawn out at the top tier.

Weights. The shelves and shelf-supports weigh from 7 to 10 lb per cu ft of book-range. Books weigh about 20 or 25 lb per cu ft of book-range. The steel deck-floor framing weighs from 4 to 6 lb per sq ft of gross area of deck-floor. Marble floor-slabs, 1¼ in thick, weigh about 20 lb per sq ft, and ¾-in rough, plate-glass slabs, about 10 lb per sq ft of net area.

Book-Capacities. Book-capacities per linear foot of shelf may be figured on the following basis: law-books, 5 volumes; reference books, 6 volumes; scientific books, 7 volumes; general literature, from 8 to 10 volumes. The average in the Library of Congress is 8½ volumes per linear foot. An ordinary stack-tier, 7 shelves high with double-faced ranges 16 in deep (or 8-in shelves) and aisles 32 in wide, with a reasonable allowance made for cross-aisles, stairways, etc., will contain about 22 volumes per sq ft of gross area.

CLASSICAL MOLDINGS

Moldings are so called because they are of the same shape throughout their length as though the whole had been cast in the same mold or form. The regular moldings, as found in remains of classic architecture, are eight in number, as shown in the accompanying illustration, and are known by the following names: The last two are commonly called, also, OGEE MOLDINGS. Some of these terms are derived thus: FILLET, from the French word FIL, a thread; ASTRAGAL, from ASTRAGALOS, a bone of the heel, or the curvature of the heel; BEAD, because this molding, when properly carved, resembles a string of beads; TORUS, or TORE, the Greek for rope, which it resembles when on the base of a column; SCOTIA, from SKOTIA, darkness, because of the strong shadow cast in its hollow, and which is increased by the projection of the torus above it; OVOLO, from OVUM, an egg, which this member resembles when carved, as in the Ionic capital; CAVETTO, from CAVUS, hollow; CYMATIUM, from KUMATON, a wave.



Characteristics of Moldings. None of these moldings is peculiar to any one of the orders of architecture; and although each has its appropriate use, it is by no means confined to any certain position in an assemblage of moldings. The use of the fillet and also of the astragal and torus, which resemble ropes, is to bind the parts. The ovolo and cyma-reversa are strong at their upper extremities, and are therefore used to support projecting parts above them. The cyma-recta and cavetto, being weak at their upper extremities, are not used as supporters, but are placed uppermost to cover and shelter the upper

parts. The scotia is introduced in the base of a column to separate the upper and lower torus, and to produce a pleasing variety and relief. The form of the bead and that of the torus are the same; the reason for giving distinct names to them is that the torus, in every order, is always considerably larger than the bead and is placed among the base-moldings, whereas the bead is never placed there, but on the capital or entablature. The torus, also, is seldom carved, whereas the bead is; and while the torus, among the Greeks, was frequently elliptical in its form, the bead retains its circular shape. While the scotia is the reverse of the torus, the cavetto is the reverse of the ovolo, and the cyma-recta and cyma-reversa are combinations of the ovolo and cavetto.

THE CLASSICAL ORDERS *

Origin of the Orders. "In the classical styles several varieties of column and entablature are in use. These are called the ORDERS. Each order comprises a COLUMN with a BASE, SHAFT and CAPITAL, with or without a PEDESTAL, with its BASE, DIE and CAP, and is crowned by an ENTABLATURE, consisting of ARCHITRAVE, FRIEZE and CORNICE. The entablature is generally about one-fourth as high as the column, and the pedestal one-third, more or less. Among the Greeks the forms used by the Doric race, which inhabited Greece itself and had colonies in Sicily and Italy, were much unlike those of the Ionic race, which inhabited the western coast of Asia Minor, and whose art was greatly influenced by that of Assyria and Persia. Besides the IONIC and DORIC styles, the Romans devised a third, which employed brackets, called MODILLIONS, in the cornice, and was much more elaborate than either of them; this they called the CORINTHIAN. They used also a simple Doric called the TUSCAN, and a cross between the Corinthian and Ionic called the COMPOSITE. These are the FIVE ORDERS. The ancient examples vary much among themselves and differ in different places, and in modern times still further varieties are found in Italy, Spain, France, Germany and England. The best known and most admired forms for the orders are those worked out by Giacomo Barozzi da Vignola in the sixteenth century from the study of ancient examples."

The Tuscan Order. "The distinguishing characteristic of the TUSCAN ORDER (Fig. 1) is simplicity. Any forms of pedestal, column and entablature that show but few moldings, and those plain, are considered to be TUSCAN."

The Doric Order. "The distinguishing characteristics of the DORIC ORDER are features in the FRIEZE and in the BED-MOLD above it called TRIGLYPHS and MUTULES, which are supposed to be derived from the ends of beams and rafters in a primitive wooden construction with large beams. Under each triglyph, and beneath the TÆNIA which crowns the architrave, is a little filet called the REGULA. Under the regula are six long drops, called GUTTÆ, which are sometimes conical, sometimes pyramidal. There are also either eighteen or thirty-six short cylindrical guttæ under the soffit of each mutule. The guttæ are supposed to represent the heads of wooden pins, or treenails. Two different Doric cornices are in use, the MUTULARY with bracket and the DENTICULATED with dentils, the principal difference being in the BED-MOLD." The order shown in Fig. 2 has the denticulated cornice.

* The paragraphs in quotation-marks are taken from The American Vignola by Professor W. R. Ware, by permission of the owners of the copyright, the International Textbook Company, Scranton, Pa., proprietors of the International Correspondence Schools. The engravings were made especially for this book, and correspond with the original drawings prepared by Giacomo Barozzi da Vignola.

The Ionic Order. "The prototypes of the IONIC ORDER (Fig. 3) are to be found in Persia, Assyria, and Asia Minor. It is characterized by BANDS in the architrave and DENTILS in the bed-mold, both of which are held to represent small sticks laid together to form a beam or a roof. But the most conspicuous and distinctive feature is the SCROLLS which decorate the CAPITAL of the

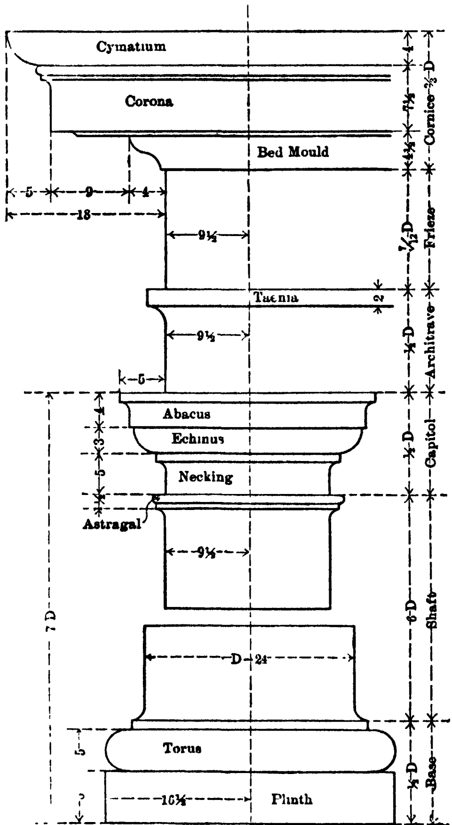


Fig. 1. The Tuscan Order

column. These have no structural significance, and are purely decorative forms derived from Assyria and Egypt. Originally the Ionic order had no FRIEZE and no ECHINUS in the capital. These were borrowed from the Doric order, and, in like manner, the dentils and bands in the Doric were borrowed from the Ionic. The Ionic frieze was introduced in order to afford a place for sculpture, and was called by the Greeks the ZOOPHORUS, or figure-bearer. The typical IONIC BASE is considered to consist mainly of a SCOTIA, as in some

Greek examples. It is common, however, to use instead what is called the ATTIC BASE, consisting of a SCOTIA and two FILLETS between two large TORUSES, mounted on a PLINTH, the whole half a diameter high. The plinth occupies the lower third, or one-sixth of a diameter. Vignola adopted for his

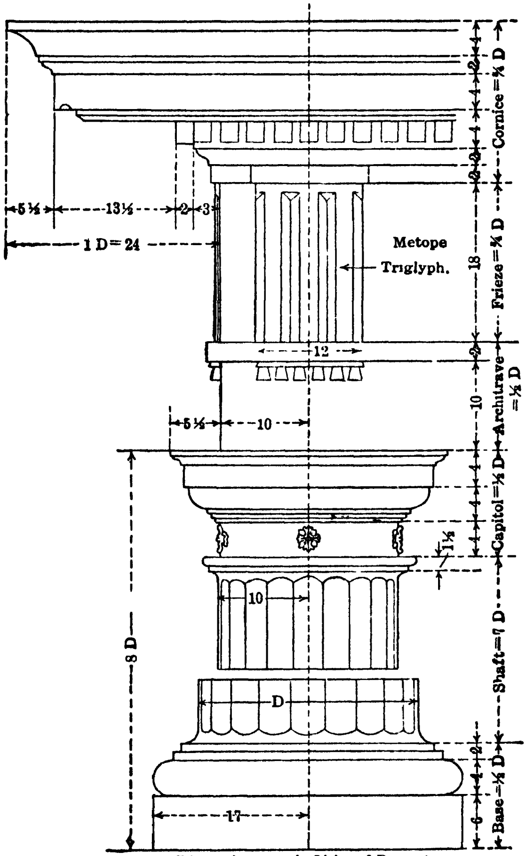

Fig. 2. The Doric Order

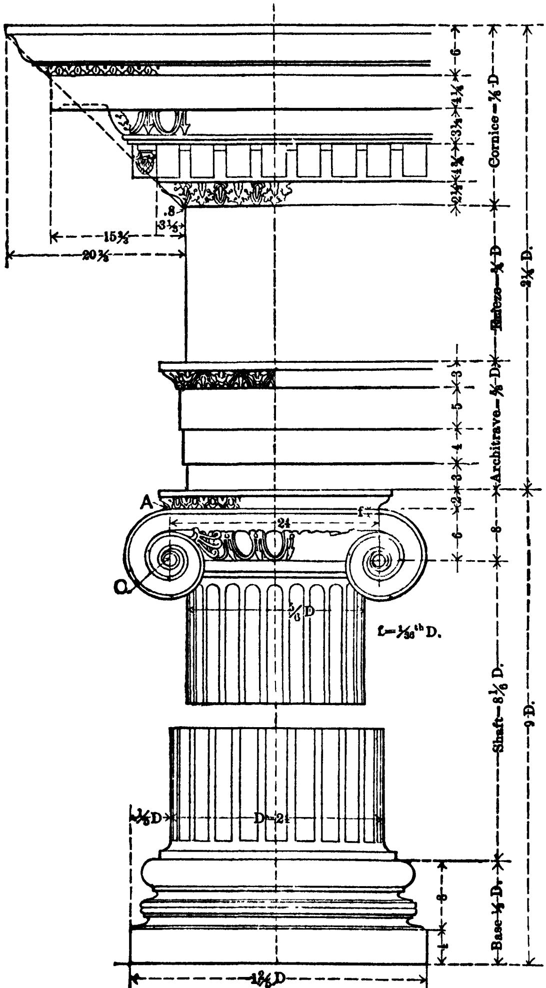
Ionic order a modification of the Attic base, substituting for the single large scotia two small ones, separated by one or two beads and fillets, and omitting the lower torus." This is the base shown in Fig. 3. "The Ionic frieze is plain, except for the sculpture upon it. It sometimes has a curved outline, as if ready to be carved, and is then said to be PULVINATED, from pulvinar, a bolster, which it much resembles. The SHAFT of the column is ornamented

with twenty-four FLUTINGS, semicircular in section, which are separated not by an ARRIS, but by a FILLET of about one-fourth their width. This makes



Dimensions are in 24ths of Diameter.

Fig. 3. The Ionic Order

the flutings only about two-thirds as wide as the Doric channels, or about one-ninth of a diameter, instead of one-sixth."

To Describe the Ionic Volute. There are several methods of doing this, the simplest being by means of centers found as shown by the diagram in Fig. 4. First locate the center of the EYE $\frac{1}{4}$ *D* vertically below the point *A*, Fig. 3. Then describe a circle with a diameter equal to $\frac{1}{18}$ *D*, to form the eye. Inside of this circle inscribe a square at 45 degrees to a horizontal; then draw the axes 1–3 and 2–4, and divide each of these into six equal parts. Then with the point 1 as a center, and a radius extending to *A*, Fig. 3, draw a quarter-circle to line 1–2 produced, with 2 as a center, continue the curve until it intersects 2–3 produced; and so on. The centers for the outer curve of the volute are at the points 1, 2, 3, 4, 5, 6, etc. For the centers for the inner curve, start with a point one-third the way from 1 to 5, then a point one-third the way from 2 to 6, and so on.

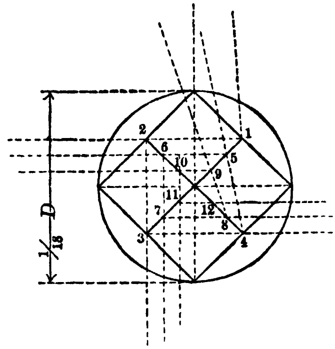


Fig. 4. The Ionic Volute

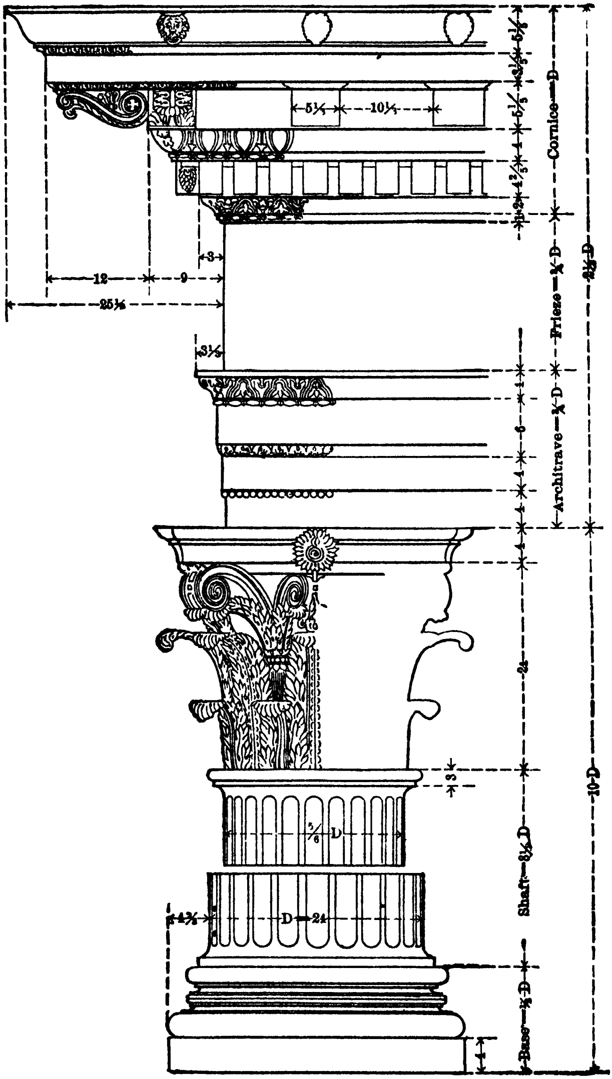
The Corinthian Order. "The three distinguishing characteristics of the CORINTHIAN ORDER (Fig. 5) are a tall, bell-shaped capital, a series of small brackets called MODILLIONS, which support the cornice instead of MUTULES, in addition to the DENTILS, and a general richness of detail which is enhanced by the use of the ACANTHUS LEAF in both capitals and modillions. Here, again, the ATTIC BASE is commonly used, but sometimes, especially in large columns, a base is used which resembles Vignola's IONIC BASE, except that it has two BEADS between the SCOTIAS instead of one, and also a lower TORUS. The SHAFT is fluted like the Ionic shaft, with twenty-four semicircular FLUTINGS, but these are sometimes filled with a convex molding or CABLE to a third of their height. Almost all the buildings erected by the Romans employ the Corinthian order."

The Composite Order. "The COMPOSITE ORDER is a heavier Corinthian, just as the Tuscan is a simplified Doric. The chief proportions are the same as in the Corinthian order, but the details are fewer and larger. It owes its name to the CAPITAL, in which the two lower rows of leaves and the CAULICOLI are the same as in the Corinthian. But the caulicoli carry only a stunted LEAF-BUD, and the upper row of leaves and the sixteen VOLUTES are replaced by the large ECHINUS, SCROLLS and ASTRAGAL of a complete Ionic capital. Vignola's composite entablature differs from his Ionic chiefly in the shape and size of the DENTILS. They are larger, and are more nearly square in elevation, being one-fifth of a diameter high and one-sixth wide, the INTERDENTIL being one-twelfth, and they are set one-fourth of a diameter apart, on centers. The composite capital is employed in the Arch of Titus in Rome, and elsewhere, with a Corinthian entablature, and the BLOCK CORNICE occurs in the so-called FRONTISPIECE of Nero, as well as in the temple at Athens, in connection with a Corinthian capital."

Egyptian Style. The architecture of the ancient Egyptians is characterized by boldness of outline, solidity, and grandeur. The principal features of the EGYPTIAN STYLE of architecture are: uniformity of plan, never deviating from right lines and angles; thick walls, having the outer surface slightly



Dimensions are in 24ths of Diameter

THE CORINTHIAN ORDER

Fig. 5. The Corinthian Order

deviating inwardly from the perpendicular; the whole building low; roof flat, composed of stones reaching in one piece from pier to pier, these being supported by enormous columns, very stout in proportion to their height; the shaft sometimes polygonal, having no base, but with a great variety of handsome CAPITALS, the foliage of these being of the palm, lotus and other leaves;

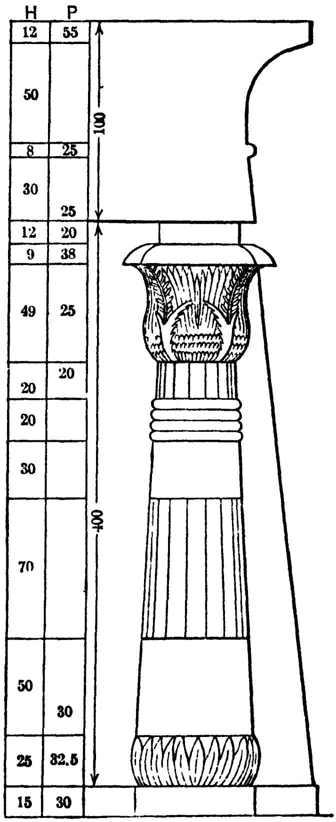


Fig. 6. An Egyptian Order. Diameter Divided into Sixty Parts

ENTABLATURES having simply an ARCHITRAVE, crowned with a huge CAVETO ornamented with sculpture; and the INTERCOLUMNIATION very narrow, usually 1½ diameters and seldom exceeding 2½. A great dissimilarity exists in the proportions, forms and general features of Egyptian columns. For practical use the column shown in Fig. 6 may be taken as a standard of the Egyptian style.

LIGHTNING CONDUCTORS *

Terms and Definitions. Air Terminal. The combination of elevation-rod and brace, or footing placed on upper portions of structures, together with tip or point if used.

Conductor. The portion of a protective system designed to carry the current of a lightning discharge from air terminal to ground.

Copper-clad Steel. Steel with a coating of copper welded to it as distinguished from copper-plated or copper-sheathed material.

Elevation-Rod. The vertical portion of conductor in an air terminal by means of which it is elevated above the object to be protected.

Ground Connection. A buried body of metal with its surrounding soil and a connecting conductor which together serve to bring an object into electrical continuity with the earth.

Conductors. (a) Materials. The materials of which protective systems are made shall be relatively resistant to corrosion or shall be acceptably protected against corrosion. No combination of materials shall be used that forms an electrolytic couple of such nature that in the presence of moisture corrosion is accelerated.

(1) COPPER. Where copper is used it shall be of the grade ordinarily required for commercial electrical work, generally designated as being of 98% conductivity when annealed.

(2) ALLOYS. Where alloys of metals are used they shall be substantially as resistant to corrosion as copper under similar conditions.

The importance of resistance to corrosion of lightning-conductor materials should be emphasized, because corrosion, either soil or atmospheric, leads to deterioration and consequent impairment of the initial degree of reliability of a system and should be forestalled wherever possible. It may also be pointed out that atmospheric conditions in certain seacoast sections of the United States, notably South Atlantic and Gulf coasts, are known to be destructive to galvanized steel, and in such regions galvanized steel should be used with caution, a preference being given to copper. Copper is also to be preferred where corrosive gases are encountered, but it needs to be reinforced with a lead coating under exceptional conditions, such as are found near the tops of smokestacks.

(b) Form and Size. Conductors may be in the form of CABLE, TUBE, STRIP, or ROD, having ROUND, SQUARE, STAR or other solid cross-section. The following give minimum sizes and weights:

(1) COPPER-CABLE. Copper-cable conductors shall weigh not less than 187.5 lb per 1 000 ft (0.279 kg per m). The size of any wire of a cable shall be not less than No. 17 A.W.G. (0.045 in = 0.114 cm diameter).

(2) COPPER TUBE, COPPER SOLID SECTION. Tube or solid-section conductors of copper shall weigh not less than 187.5 lb per 1000 ft (0.279 kg per m). The thickness of any tube wall shall be not less than No. 20 A.W.G. (0.032 in = 0.081 cm). The thickness of any copper ribbon or strip shall be not less than No. 20 A.W.G. (0.051 in = 0.129 cm).

* The information here given is taken from the U. S. Department of Commerce publication, "Code for Protection against Lightning," approved April 4, 1929, by the American Standards Association. Additional information on the subject may be obtained from the Department of Commerce or from the Copper Brass Research Association, 25 Broadway, New York City.

(c) **Joints.** Joints in conductors shall be as few in number as practicable, and where they are necessary they shall be mechanically strong, well made, and provide ample electrical contact. The latter requirement is to be regarded as met by a contact area not less than double the conducting cross-sectional area of the conductor.

(1) Mechanical Strength. On structures exceeding 60 ft in height, joints shall be so constructed that their mechanical strength in tension as shown by laboratory tests is not less than 50% of that of the smallest of the several sections of conductor which are joined.

(2) Electrical Resistance. Joints shall be so made that they have an electrical resistance not in excess of that of 2 ft of conductor.

(d) **Fastenings.** Conductors shall be securely attached to the building or other object upon which they are placed. Fastenings shall be substantial in construction, and of the same material as the conductor, or of such a nature that there will be no serious tendency toward electrolytic corrosion in the presence of moisture. Fasteners shall be spaced, in general, not over 4 ft apart.

Elevation-Rods. (a) **Size.** Elevation-rods shall be at least the equivalent in weight and stiffness of a copper tube having an outside diameter of 5/8 in (1.6 cm) and a wall thickness of No. 20 A.W.G. (0.032 in = 0.081 cm).

(b) **Form.** Elevation-rods may be of any form of solid or tubular cross-section.

(c) **Height.** The height of an elevation-rod shall be such as to bring the tip not less than 10 in (25.4 cm) above the object to be protected.

(d) **Braces.** Elevation-rods shall be amply secured against overturning either by attachment to the object to be protected or by means of substantial tripod or other braces which shall be permanently and rigidly attached to the building.

(1) Materials. The material of which braces are constructed shall be at least the equivalent in strength and stiffness of 1/4 in (0.625 cm) round iron, and the nails or screws used in erecting must comply with the requirements of conductor materials as outlined above in resistance to corrosion or protection against corrosion.

(2) Form and Construction. Braces shall be assembled by means of riveted joints or joints of equivalent strength. Preference should be given to tripod or four-legged braces, and when in place the feet should be spread until the distance between them approximates one-third the height of the brace.

(3) Guides. Where elevation-rods are more than 24 in high, braces shall have guides for holding the elevation-rod at two points located approximately as follows: the lower at a distance above the foot of the rod equal to one-third of its height, the upper at a distance above the lower, equal to one-fourth the height of the rod.

Where elevation-rods are 24 in high or less, braces with a single guide may be used, holding the rod approximately midway of its height. Ten-inch (25.4 cm) elevation-rods may be braced by means of substantial footings.

Location of Air Terminals. (a) **General.** Air terminals shall be provided for all structural parts that are likely to receive, and be damaged by a stroke of lightning.

(b) **Projections.** In the case of projections such as gables, chimneys and ventilators, the air terminal shall be placed on, or attached to, the object to be protected where practicable, otherwise within 2 ft (61 cm) of it.

(c) Ridges, Parapets and Edges of Flat Roofs. Along ridges, parapets and edges of flat roofs, air terminals shall be spaced at intervals not exceeding 25 ft (7.62 m), and intermediate terminals need not be closer than 12.5 ft (3.81 m).

(d) Metal Projections and Parts of Buildings. Ventilators, smokestacks and other objects, that are likely to receive, but not be damaged by, a stroke of lightning, need not be provided with air terminals but shall be securely bonded to the lightning-conductor with metal of the same weight per unit length as the main conductor.

(e) Coursing of Conductors. Conductors shall, in general, be coursed over roofs and down the corners and sides of buildings in such a way as to constitute, as nearly as local conditions will permit, an inclosing network.

(f) Roof-Conductors. Roof-conductors shall be coursed along contours such as ridges, parapets, and edges of flat roofs, and where necessary over flat surfaces, in such a way as to join each air terminal to all the rest.

(g) Down-Conductors. Down-conductors shall preferably be coursed over the extreme outer portions of buildings, such as corners, due consideration being given to the best places for making ground connections and to the location of air terminals.

There shall be at least two down-conductors on any type of building, and these shall be run so as to be as widely separated as practicable. Additional down-conductors shall be installed where necessary to avoid DEAD ENDS, branch conductors ending at air terminals, which exceed 16 ft (4.88 m) in length. Single down-conductors descending flag-poles, spires and similar structures which are adjuncts of buildings shall not be regarded as dead ends, but shall be treated as air terminals.

(h) Bends. No bends in a conductor which embraces a portion of a building, such as an eave, shall have a radius of less than 8 in (20 3 cm). The angle of any turn shall not exceed 90°, and conductors shall everywhere preserve a downward or approximately horizontal course.

VACUUM-CLEANING *

General Description. Vacuum-cleaning of all types has become the recognized standard for cleaning of every description, from the ordinary household to hotels, schools, office-buildings, theaters and industrial plants. The difficulties encountered in the early installations have been largely overcome by equipment of modern design.

Types of Vacuum-Cleaners. There are three recognized types of vacuum-cleaners. First, the HOUSEHOLD type which is largely used as a substitute for the broom in household use. Second, the HEAVY-DUTY PORTABLE type, designed particularly for industrial applications where the machine is subjected to severe use. Third, the CENTRAL CLEANING SYSTEM sometimes designated as the INSTALLED SYSTEM.

The CENTRAL SYSTEM is of the most interest to the architect, as it is this type that is generally used in the modern hotel, school, office building, theater, etc. The fact that this equipment is installed during the construction of a building, and should be included in the general contract, makes it important for the architect to obtain accurate information. The equipment consists of a vacuum-pump and dirt separator located in the basement, from which a

* From data given by the Spencer Turbine Co.

piping system extends throughout the building. Manufacturers of equipment have reliable data concerning the size of equipment necessary for the various types of buildings and should be consulted on the size of the machine, pipe sizes, and the design of the tool.

Irrespective of other specifications, there should be included what is known as the standard orifice performance test, namely: that 2 in Hg. with a $\frac{7}{8}$-in opening, or 3 in Hg. with a $\frac{5}{8}$-in opening, be required for each sweeper the machine is designed to operate. These measurements are to be taken at the end of 50 ft of $1\frac{1}{2}$-in hose distributed at various points throughout the building. The manufacturers of equipment are always willing to supply engineering data and specification sheets and should be consulted in order to insure a correct installation.

WATERPROOFING FOR FOUNDATIONS

The Waterproofing of Substructure Work, is, comparatively speaking, a modern branch of engineering. It is only within recent years that it has become necessary to construct deep basements for buildings. In the past, the more important structures, such as cathedrals, capitols, state-buildings and the like, were usually built upon high ground, and water was prevented from entering the basements of such buildings by means of drainage. Waterproofing, as we now know it, was generally unnecessary. With the advent of the so-called skyscrapers, however, requiring large mechanical plants, deep basements became an actual necessity, and as these basements are usually carried below ground-water level, and in many instances below tide-level, the question became one of utmost importance. Like almost every detail of a modern building, waterproofing is a specialty. Each building presents its own problems, and the safest plan is to leave the solution of these problems to some one expert in the knowledge of waterproofing who has made it a special study and knows how best to overcome the existing difficulties. It may be laid down as an invariable rule that, where conditions are at all serious, the owner or the general contractor will save money in the long run if he employs the services of an expert waterproofer to place his waterproofing-seal, regardless of the method he wishes to use.

Pressure-Resistance Versus Waterproofing. In waterproofing large basements where actual pressure exists, it is a question for the engineer to decide whether it is more economical to attempt to secure an absolute PRESSURE-JOB or a WATER-PROOF JOB in connection with a drainage system. As a general rule, it may be stated that where a building is generating its own power, it is more economical to use a drainage system with an open sump than to construct a pressure-cellar, the cost of pumping being much less than the interest charges on the cost of a floor-slab sufficiently strong to withstand the pressure.

Waterproofing Concrete Foundations. The three following subdivisions of this subject, discussing the causes of permeability of concrete, the addition of substances to render it more water-proof, and the treatment of its surfaces to make it less permeable, embody the conclusions of Committee D-8 of the American Society for Testing Materials: * This committee, since its organization in 1905 has, through laboratory-tests and experiments, together with examinations of work during construction and after completion, as well as the

* This article, as far as the section entitled "Burlap Saturated with Bituminous Substances," is the substance of a Report submitted to the American Society for Testing Materials.

study of literature on the subject, sought to secure sufficient information to enable it to formulate definite methods for securing water-proof concrete structures. The work of the committee was complicated by reason of the facts that there seemed to be so little concordance between results of tests obtained under laboratory-conditions and in the field and that it was necessary to extend its investigations over a period of years in order to determine the permanency of the action noted. The committee reported that while it had not been able to arrive at sufficiently definite conclusions to enable it to formulate specifications for the making of concrete structures water-proof or for materials to be used in such work, it had reached certain general conclusions which might be of assistance to the constructor in securing the desired result of impermeable concrete. Early in the investigation, the work was found to subdivide naturally into three branches, and the conclusions reached will be grouped in order under these subdivisions, which are:

(1) The determination of causes of the permeability of concrete as usually made from mixtures of Portland cement, sand and stone, or other coarse aggregate, in proportions of from 1 of cement, 2 of sand and 4 of stone, to 1 of cement, 3 of sand and 6 of stone, and the best methods of avoiding these causes.

(2) The rendering of concrete more water-proof by adding to ordinary mixtures of cement, sand and stone, other substances which, either by their void-filling or repellent action, would tend to make the concrete less permeable.

(3) The treatment of exposed surfaces after the concrete or mortar has been put in place and hardened more or less, either by penetrative, void-filling or repellent liquids, making the concrete itself less permeable; or by extraneous protective coatings, preventing water from having access to the concrete.

Considering these several subdivisions separately and in the order named, the committee arrives at the following conclusions:

(1) **Causes of Permeability of Concrete.** In the laboratory and under test-conditions where properly graded and sized coarse and fine aggregates are used, in mixtures ranging from 1 of cement, 2 of sand and 4 of stone, to 1 of cement, 3 of sand and 6 of stone, impermeable concrete can invariably be produced. Even with sand of poor granulometric composition, with mixtures as rich as 1 of cement, 2 of sand and 4 of stone, permeable concrete is seldom, if ever, found and is a rare occurrence with mixtures of 1 of cement, 3 of sand and 6 of stone. But the fact remains, nevertheless, that the reverse often obtains in actual construction, permeable concretes being encountered even with mixtures of 1 of cement, 2 of sand and 4 of stone and are of frequent occurrence where the quantity of the aggregate is increased. This the committee attributes to:

(*a*) Defective workmanship, resulting from improper proportioning, lack of thorough mixing, separation of the coarse aggregate from the fine aggregate and cement in transporting and placing the mixed concrete, lack of density through insufficient tamping or spading, improper bonding of work-joints, etc.

(*b*) The use of imperfectly sized and graded aggregates.

(*c*) The use of excessive water, causing shrinkage-cracks and formation of laitance-seams.

(*d*) The lack of proper provision to take care of expansion and contraction, causing subsequent cracking.

Theoretically, none of these conditions should prevail in properly designed and supervised work, and they are avoided in the laboratory and in the field, under test-conditions, where speed of construction and cost are negligible items, instead of being governing features as they must be in actual construction. Properly graded sands and coarse aggregates are rarely, if ever, found

in nature in sufficient quantities to be available for large construction, and the effect of poorly graded aggregates in producing permeable concrete is aggravated by poor and inefficient field-work. Even if the added expense of screening and remixing the aggregates could be afforded, so as to secure proper granulometric composition to give the density required to make untreated concretes impermeable, it is seemingly often a commercial impossibility on large construction to obtain workmanship even approximating that found in laboratory-work.

(2) **Addition of Foreign Substances to Cement Before or During Mixture.** The committee finds that in consequence of the conditions outlined above, substances calculated to make the concrete more impermeable, either incorporated in the cement or added to the concrete during mixing, are often used. This has resulted in the development and placing on the market of numerous patented or proprietary waterproofing-compounds, the composition of which is more or less of a trade-secret. While it has been impossible for the committee to test all of the special waterproofing-compounds being placed on the market, it has investigated a sufficient number of these, as well as the use of certain very finely divided, naturally occurring or readily obtainable commercial mineral products, such as finely ground sand, colloidal clays, hydrated lime, etc., to form a general idea of the value of the different types. The committee finds:

(*a*) That the majority of patented and proprietary integral compounds tested have little or no immediate or permanent effect on the permeability of concrete and that some of these even have an injurious effect on the strength of mortar and concrete in which they are incorporated

(*b*) That the permanent effect of such integral waterproofing-additions, if dependent on the action of organic compounds, is very doubtful.

(*c*) That in view of their possible effect, not only upon the early strength, but also upon the durability of concrete after considerable periods, no integral waterproofing-material should be used unless it has been subjected to long-time practical tests under proper observation to demonstrate its value, and unless its ingredients and the proportion in which they are present are known.

(*d*) That in general, more desirable results are obtainable from inert compounds acting mechanically, than from active chemical compounds whose efficiency depends on change of form through chemical action after addition to the concrete.

(*e*) That void-filling substances are more to be relied upon than those whose value depends on repellent action.

(*f*) That, assuming average quality in sizing of the aggregates and reasonably good workmanship in the mixing and placing of the concretes, the addition of from 10 to 20% of very finely divided void-filling mineral substances may be expected to result in the production of concrete which, under ordinary conditions of exposure, will be found impermeable, provided the work-joints are properly bonded, and cracks do not develop on drying, or through change in volume due to atmospheric changes, or by settlement.

(3) **External Treatment.** While external treatment of concrete would not be necessary if the concrete itself, either naturally or by the addition of waterproofing-material, was impermeable to water, it has been found in practice that in large construction, no matter how carefully the concrete itself has been made, cracks are apt to develop, due to shrinkage in drying out, expansion and contraction under change of temperature and moisture-content, and through settlement. It is, therefore, often advisable in important construction to anticipate and provide for the possible occurrence of such cracks by external

treatment with a protective coating. Such coating must be sufficiently elastic and cohesive to prevent the cracks extending through the coating itself. The application of merely penetrative void-filling liquid washes will not prevent the passage of water due to cracking of the concrete. The committee has, therefore, considered surface-treatment under two heads:

(*a*) Penetrative void-filling liquid washes.

(*b*) Protective coatings, including all surface-applications intended to prevent water coming in contact with the concrete.

Penetrative Washes. While some penetrative washes may be efficient in rendering concrete water-proof for limited periods, their efficiency may decrease with time and it may be necessary to repeat such treatment. Some of these washes may be objectionable, due to discoloring the surface to which they are applied. The committee, therefore, believes that the first effort should be made to secure a concrete that is impermeable in itself and that penetrative void-filling washes should only be resorted to as a corrective measure.

Protective Coatings. While protective extraneous bituminous or asphaltic coatings are unnecessary, so far as the major portion of the surface of the concrete is concerned, provided the concrete, either in itself or through the addition of integral compounds, is made impermeable, they are valuable as a protection where cracks develop in a structure. It is therefore recommended that a combination of inert void-filling substances and extraneous waterproofing be adopted in especially difficult or important work.

Bituminous or Asphaltic Coatings. Considering the use of bituminous or asphaltic coatings, the committee finds:

(*a*) That such protective coatings are often subject to more or less deterioration with time, and may be attacked by injurious vapors or deleterious substances in solution in the water coming in contact with them.

(*b*) That the most effective method for applying such protection is either the setting of a course of impervious brick dipped in bituminous material into a solid bed of bituminous material, or the application of a sufficient number of layers of satisfactory membranous material cemented together with hot bitumen.

(*c*) That their durability and efficiency are very largely dependent on the care with which they are applied. Such care refers particularly to proper cleaning and preparation of the concrete to insure as dry a surface as possible before application of the protective covering, the lapping of all joints of the membranous layers, and their thorough coating with the protective material. The use of this method of protection is further desirable because proper bituminous coverings offer resistance to stray electrical currents, the possible attack from which is referred to in succeeding paragraphs.

Rich Mixtures. So far, the committee has considered only concretes of the usual proportions, namely, those ranging from 1 of cement, 2 of sand and 4 of stone, to 1 of cement, 3 of sand and 6 of stone. It has been suggested that impermeable concretes could be assured by using mixtures considerably richer in cement. While such practice would probably result in an immediate impermeable concrete, it is believed by many that the advantage is only temporary, as richer concretes are more subject to check-cracking and are less constant in volume under changes of conditions of temperature, moisture, etc. Therefore, the use of more cement in mass-concrete would cause increased cracking, unless some means of controlling the expansion and contraction is discovered. With reinforced concretes the objection is not so great, as the tendency to cracking is more or less counteracted by the reinforcement.

Fine Flour Mixtures. It has also been suggested that the presence in the cement of a larger percentage of very fine flour might result in the production of a denser and more impermeable concrete, through the formation of a larger amount of colloidal gels. Neither of these suggestions has been especially investigated by the committee. Both appeal to the committee, however, for the reason that they substitute active cementitious substances for the largely inactive void-filling materials previously recommended, thus increasing the strength of the concrete.

Character of Workmanship. In conclusion, the committee would point out that no addition of waterproofing-compounds or substances can be relied upon to completely counteract the effect of bad workmanship, and that the production of impermeable concrete can only be hoped for where there is determined insistence on good workmanship.

Saline Waters. Electrical Action. The production of impermeable concrete has assumed greater importance since the appointment of this committee, owing to the well-known injurious action of saline or alkaline waters and to the suggested possible effect of the moisture in concrete occasioning or aggravating electrical action from stray currents. Originally, the question of waterproofing involved mainly the physical troubles resulting from water passing through concrete without any special consideration of its effect on its durability, other than a gradual leaching out of the cement. Recent developments suggest the possibility that, owing to the increased conductivity of damp concrete to electrical currents, such currents, if present, may so affect damp concrete as to seriously lessen its integrity; and this possibility further emphasizes the importance of the recommendation that no waterproofing-compound of unknown chemical composition be added to concrete, as recent tests seem to show that the action of electrical currents is aggravated by the presence of certain solutions.

Burlap * Saturated with Bituminous Substances for Use in Waterproofing. The following excerpts are taken from American Society for Testing Materials, Serial Designation: D 174–25, Standard Specifications. "These specifications cover bituminized jute fabric, composed of burlap waterproofed with either asphalt or coal-tar pitch, as specified by the purchaser, for use in the membrane system of waterproofing. In the process of manufacture, the dry burlap shall be thoroughly and uniformly waterproofed with an asphaltic or coal-tar pitch saturant at a temperature and speed which will not injure the fabric. This shall be accomplished by passing the fabric through the saturant and then calendering it in the presence of heat, whereupon it shall be cooled and wound into rolls. The finished material shall be free from visible external defects such as ragged or untrue edges, breaks, rents or cracks. The meshes of the fabric shall not be completely closed or sealed by the process of saturation, but there shall be sufficient porosity maintained to allow successive moppings of the plying cement to seep through. The selvage shall not measure over $3/16$ in. The roll shall be capable of being unrolled easily at atmospheric temperatures above 50° F. (10° C.) without sticking together in such a manner as to injure the fabric. The surface of the fabric shall not be coated or covered with talc or other substances which would tend to interfere with the adhesion between the fabric and the plying cement. The use of silica or wood flour will be permitted. The surface shall be uniformly smooth and free from irregularities, folds or knots."

*** For Standard Specifications for Woven Cotton Fabrics Saturated with Bituminous Substances for Use in Waterproofing, see A. S. T. M. Designation: D 173–27.**

Bituminous Grout for use in Waterproofing below Ground-level. The following excerpts are taken from Standard Specifications of the American Society for Testing Materials, Serial Designation: D 171–25. "These specifications cover the materials for bituminous grout suitable for use in waterproofing below ground-level, either as a protective covering of membrane systems of waterproofing or for bedding brick or filling the joints or flooding the surface of a brick protective covering. The grade of bituminous grout covered by these specifications is suitable for waterproofing tunnels, subways, etc. This bituminous grout is a mixture of substantially 45 parts by weight of bituminous binder and 55 parts by weight of mineral aggregate as coarse as sand, which becomes sufficiently fluid, when heated to approximately 149° C. (300° F.), to flow without mechanical manipulation, and which on cooling congeals to a compact mass.

"The bituminous binder shall consist of either asphalt binder or coal-tar pitch as follows:

"(*a*) The asphalt binder shall conform to the requirements of the Standard Specifications for Asphalt for Use in Dampproofing and Waterproofing Below Ground-Level (Serial Designation: D 40) of the American Society for Testing Materials.

"(*b*) The coal-tar pitch shall conform to either of the following tentative specifications of the American Society for Testing Materials:

"(1) Standard Specifications for High-Carbon Coal-Tar Pitch for Use in Dampproofing and Waterproofing below Ground-Level (Serial Designation: D 42).

"(2) Standard Specifications for High-Bitumen Coal-Tar Pitch for Use in Dampproofing and Waterproofing below Ground-Level (Serial Designation: D 200).

"The mineral aggregate shall consist of silicious sand, all of which will pass a 20-mesh sieve, and not more than 5% of which will pass a 200-mesh sieve."

Waterproofing by External Linings of Brick, Tar, or Asphalt, and Felt. The oldest method of waterproofing is the one involving the use of a tar-and-felt or asphalt-and-felt seal (Fig. 1). This consists of building first a supporting wall and a supporting concrete slab to hold the seal. On the floors, this slab is usually composed of concrete, 4 in thick. The walls are generally of brick from 4 to 8 in thick, but occasionally 4-in terra-cotta tiles are used. Upon this base a swabbing of tar or asphalt is placed and before this has become cold or set, one thickness of paper, saturated with coal-tar, is laid. This paper receives a swabbing of coal-tar and asphalt and another layer of paper is placed, the operation being continued until there are three or more layers of paper with four or more swabbings of the tar or asphalt. For dampproof work, three layers of paper with four swabbings of tar are usually sufficient. For waterproofing-work not less than five and usually six layers of paper with from six to seven swabbings of tar are used. The main walls of the structure are then built against the wall-waterproofing, and after these are in place, the main concrete basement-floor is laid immediately on top of the floor-seal, the idea being to form a continuous waterproof seal enveloping the entire basement below grade. The difficulties of this system consist chiefly in securing perfect laps at all points in the work, and unless extreme care is used and unless there is perfect coöperation between the waterproofer and the mason-contractor, there is apt to be a break somewhere in the seal, usually where the wall-waterproofing is supposed to be joined to the floor-work. The disadvantages of this system are due to the fact that the seal is not permanent

in all soils as the subsurface water frequently contains acids which destroy the seal. Then again, the seal may be easily punctured by the mason-contractor in building his wall against it or in laying the concrete floor upon the flat work. The chief disadvantage, however, is that the waterproofing-seal is invariably buried behind a mass of masonry, either brick or concrete, which means that should there be a leak, due to either carelessness or accident, through the waterproofing-seal, it is frequently impossible to stop it. It not infrequently happens that when a leak has developed in tar-and-felt work,

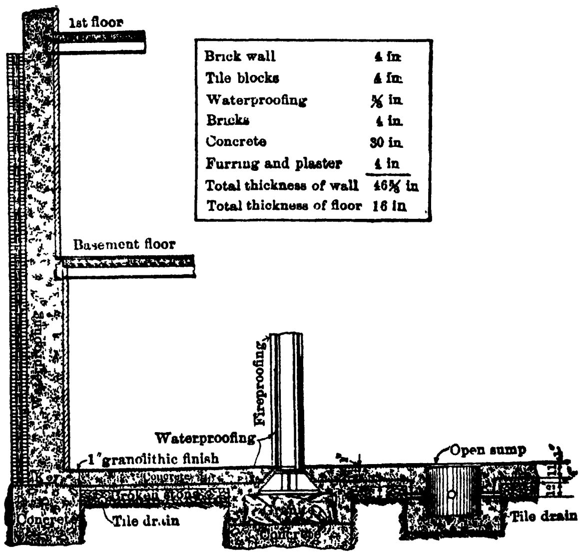

Fig. 1.* Felt-Waterproofing for Foundations

the actual presence of the water does not show opposite the leak, but following some line of least resistance, appears from 50 to 100 ft, or more, away from where the actual damage causing the leak occurs. In actual waterproofing work it is seldom attempted to secure a bottle-tight job with tar and felt. Instead, some system of drainage is installed beneath the water-proof seal which is on the floors of the building, and the water is conducted through tile or other pipes to some central sump from which it is mechanically pumped to a sewer. The purpose of the waterproofing in this case, therefore, is to concentrate or drive the water to this sump. For shallow cellars and especially dampproofing-work, this tar-and-felt method is the most economical and most frequently employed.

* Reproduced, by permission, from a pamphlet published by The Waterproofing Company, New York, and showing the greater thickness of walls and floor required for the outside-surface brick-and-felt method of waterproofing as compared with the inside-surface waterproof-cement coating. Taken from design for waterproofing in a prominent New York building. See, also, Fig 2

Waterproofing by Coating with Water-Proof Cement. For deep and difficult work a comparatively new method of waterproofing is often used (Fig. 2). This consists of placing a coating of water-proof cement upon the interior surface of the exterior walls of the building and over the upper surface of the concrete floor-slab in the basement or sub-basement. Fig. 3 shows a foundation for an engine, the concrete being waterproofed as shown. The pit is made somewhat larger than the foundation, the extra space being filled in with cinders, dry bricks or terra-cotta blocks, which may be readily removed to allow access to the bed-plate bolts for which hand-holes have been cast in

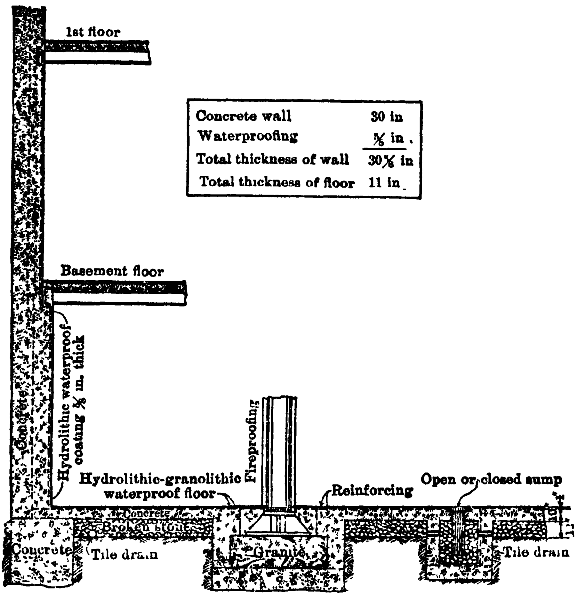

Fig. 2.* Cement Waterproofing for Foundations

the concrete, thus permitting the complete removal of the engine. The figure shows a 2-in sand cushion and a 2-in layer of planks under the engine-foundation. This is not a part of the waterproofing but is put in to prevent the communication of vibration. Fig. 4 shows reinforced-concrete floors for an engine-room and boiler-room, the concrete slab being 12 in thick under the former and 24 in thick under the latter. Both floors are covered with a 1-in course of water-proof cement. The reinforcement is put in as shown and in sizes and spacing as follows:

* From a pamphlet published by The Waterproofing Company, New York, and showing reduced total thickness of walls and floor required for the inside-surface water-proof cement method of waterproofing. Taken from design for waterproofing of the same building shown in Fig. 1. The walls and floors were put in place in the monolithic form.

12-in slab Rods in two courses	24-in slab Rods in three courses
Lower rods, 4 in on centers, 6 in from surface Upper rods, 6 in on centers, 2 in from surface For five rods, total area of cross-section is 0 703 sq in; per square foot of surface, 2.39 lb	Lowest rods, 3 in on centers, 12 in from surface Intermediate rods, 3 in on centers, 7 in from surface Upper rods, 6 in on centers, 2 in from surface For ten rods, total area of cross-section 1 4 sq in; per square foot of surface, 4 78 lb

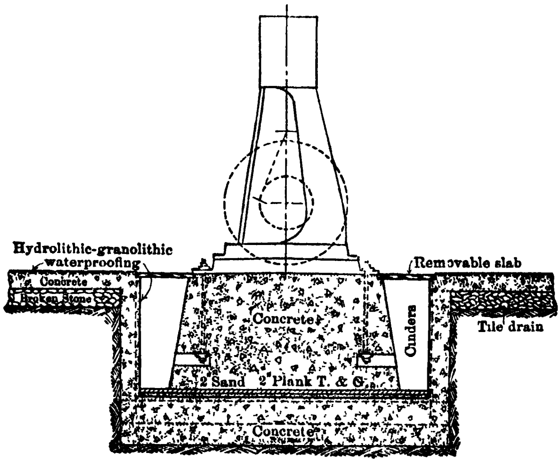

*Fig. 3.** Engine-foundation with Water-proof Cement

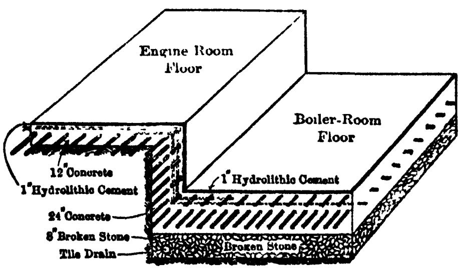

Fig. 4.* Reinforced-concrete Floor with Water-proof Cement

* Reproduced by permission of The Waterproofing Company, New York.

There are many compounds advertised to make cement or concrete water-proof. Besides these, there are water-proof cements manufactured by secret processes and applied by companies that make a specialty of waterproofing. Some of the many waterproofing-compounds have merit; but the main factors of a successful job of waterproofing are the skill and experience of the water-proofers who do the work. It is claimed that to apply cement waterproofing so as to obtain efficient results requires more skill than to apply a tar-and-felt seal; but a cement waterproofing, once properly applied, seems to possess some advantages over the older method of tar and felt. One advantage is that the waterproofing is accessible, and that if any leaks develop, they are apparent and can be readily and economically repaired by cutting out the old waterproofing and placing a new coating where the damage exists. Another advantage claimed is that cement waterproofing is generally permanent and not damaged by the ordinary acids found in solution with water in soil. By the cement method the cost of the brick supporting walls and the concrete supporting slab is eliminated as is also the corresponding cost of the necessary excavation for them; and finally, the waterproofing on the floor serves the double purpose of waterproofing and wearing-surface, thus saving the cost of the cement finish usually found in basements and sub-basements. One of the disadvantages of cement waterproofing is that the material is rigid and is fractured by any settlement of the building or contraction in the concrete upon which it is placed. Experience has shown, however, that settlement-cracks usually take place before the waterproofing contractor has left the building and that there is little or no trouble from these causes after his work is completed. Contraction-cracks in concrete, however, seem to develop at any time within twenty-four months after concrete has been placed. In order to prevent these cracks, users of the cement waterproofing have adopted a system of reinforcement in the concrete, and it is claimed that this reinforcement is, in the long run, an economy, as it permits of less concrete and gives a better and stronger floor or wall. On brick and stone walls no trouble is experienced from contraction and expansion. It should be remembered that this work is all below grade where contraction and expansion are reduced to a minimum, regardless of the materials used.

Waterproofing by Adding Substances to Cement. This is another method of waterproofing now being advocated by some. If this method could always be made efficient, it would be highly advantageous. It is claimed by the manufacturers of these compounds that in order to secure a waterproof-basement, for example, a certain percentage of the compound is to be mixed with the cement before it is incorporated in the concrete. The opponents of this method claim, however, that it is impossible to construct a basement in this way without incurring the danger of serious leaks at the joinings of one day's work with that of another; that leakage at these points of cleavage may be increased by the use of waterproofing-compounds; and that their principal merit is that they produce a very dense mass of concrete. It is always difficult to bond old concrete to new, and if concrete is made water-proof, or, in other words, nonabsorbent, the difficulty of joining new concrete to a nonabsorbent mass of old concrete is increased. This method is effective, however, and is to be recommended in work which can be carried on without interruption, such, for instance, as small elevator-pits or small swimming-pools, where the concrete can be started in the morning and completed by night or before any part of the work has had time to attain its initial set.

FORCE OF THE WIND

Relation Between the Pressure and Velocity of Wind. Accordng to experiments made in 1890 or thereabouts, by C. F. Marvin, United States Signal Service, the relation between wind-pressure and velocity is given very accurately by the formula $p = 0\ 004\ V^2$, where p is the pressure in pounds per square foot on a flat surface normal to the direction of the wind, and V the velocity of the wind in miles per hour. Smeaton considered the pressure as equal to $0.005\ V^2$. The following table, based on Marvin's formula,* is quoted by Turneaure and Ketchum.†

Table Showing the Force of the Wind

Miles per hour	Feet per minute	Feet per second	Force, in pounds, per square foot	Description
1	88	1.47	0 004	Hardly perceptible
2	176	2.93	0 014	Just perceptible
3	264	4 40	0 036	
4	352	5.87	0 064	Gentle breeze
5	440	7.33	0.1	
10	880	14 67	0.4	Pleasant breeze
15	1 320	22 0	0 9	
20	1 760	29 3	1 6	Brisk gale
25	2 200	26.6	2 5	
30	2 640	44.0	3 6	High wind
35	3 080	51.3	4 9	
40	3 520	58.6	6 4	Very high wind
45	3 960	66.0	8 1	
50	4 400	73.3	10.0	Storm
60	5 280	88.0	14 4	Great storm
70	6 160	102 7	19 6	
80	7 040	117.3	25 6	Hurricane
100	8 800	146.6	40.0	

WIND-STRESSES IN TALL BUILDINGS ‡

General Considerations. All buildings should have adequate provision for resisting wind-pressure. Walls, floors and partitions afford a certain amount of resistance, but, in high buildings, the thin walls and light partitions used in modern construction are insufficient for the purpose, and special provision to resist the stresses caused by wind should be made in the steel framing.

Steel columns for tier buildings should be used in lengths of two or more stories and spliced with sufficient plates and rivets to make them continuous with respect to transverse bending. All column splices and the connections of girders and beams to the columns should be riveted. With a properly con-

* If Marvin's formula is written $p = 0.0032\ V^2$ the values in this table will be slightly changed. The formula used by the United States Signal Service is $p = 0.004\ V^2$. The true pressure is probably somewhere between $0.005\ V^2$ and $0.004\ V^2$, near the former for very low velocities and near the latter for high velocities.

† See, also, Trautwine's Pocket-Book.

‡ This article, with slight modifications, is taken by permission from Bethlehem Structural Shapes, Bethlehem Steel Co., Bethlehem, Pa.

structed steel frame of this kind, (See Fig. 1) special wind-bracing will seldom be needed, unless the height of the building is more than twice its least base.

Higher buildings will usually require wind-bracing of some form, and as it is seldom possible to use diagonal rods between the columns, other forms of bracing may be used. Bethlehem H columns afford every facility for the construction of an ideal steel frame for buildings.

Unless specified otherwise by building codes, it is now considered good practice to provide for a horizontal wind-pressure of not less than 20 lb per sq ft on the vertical projection of exposed surfaces during erection, and 15 lb per sq ft on the vertical projection of the finished structure.

The total live, dead and wind-loads should not produce stresses exceeding those of the combined dead and live loads by more than $33\frac{1}{3}\%$.

Wind increases the compression in the leeward columns, and also produces bending in the columns and girders, all of which effects must be considered.

Exact methods, on account of their complexity, are rarely used for the calculation of wind-stresses in building frames.

Several approximate methods are in use, and are based on the general assumption that a building bent acts as a cantilever beam fixed in the ground. The wind-loads are applied horizontally, and the transverse shear in any story is distributed among the columns of the bent. The direct and bending stresses in the columns and girders due to the wind-pressure are then found by the principles of statics. The variation in methods is due primarily to the different assumptions of shear distribution among the columns and the location of the points of contraflexure.*

Cantilever Method. The cantilever method is representative of the approximate methods for calculating wind-stresses and, as modified below, is based on the following assumptions: (1) All columns in any given story have equal sections, and the direct stresses in the columns due to wind are proportional to the distances of the columns from the neutral axis of the bent; (2) the point of contraflexure of each column is at mid-height of the story and the point of contraflexure of each girder is at its mid-length; (3) the resultant of the wind-pressure acting between two successive points of contraflexure is applied at the intersection of column and girder; (4) the joints are perfectly rigid. (See Fig. 2)

Notation. $A, B, C, D, E, \ldots L,$ etc $=$ spans, in feet.

$a, b, c, d, d,'$ etc. = Distances of columns Nos. 1, 2, 3, 4, 5, etc., from the neutral axis of bent, feet.

H = distance from mid-height of the story under consideration to the top of the building, feet.

h_1 = height of the story under consideration, feet.

h_2 = height of story above, feet.

$$h = \frac{h_1}{2} + \frac{h_2}{2}.$$

W = wind-load acting on height H, pounds.

P = wind-load acting on story height h, pounds.

l = distance from mid-height of the story under consideration to the center of gravity of the wind-load W.

M_A, M_B, M_C, M_D, etc. = bending moments at ends of girders in the corresponding spans A, B, C, D, etc., foot-pounds.

M_1, M_2, M_3, M_4, etc. = bending moments of corresponding columns Nos. 1, 2, 3, 4, etc., at top and bottom of story under consideration, foot-pounds.

* Detailed descriptions of these methods may be found in current text-books.

D_1, D_2, D_3, D_4, etc. = direct stresses in the corresponding columns Nos. 1, 2, 3, 4, etc., in story under consideration, pounds.

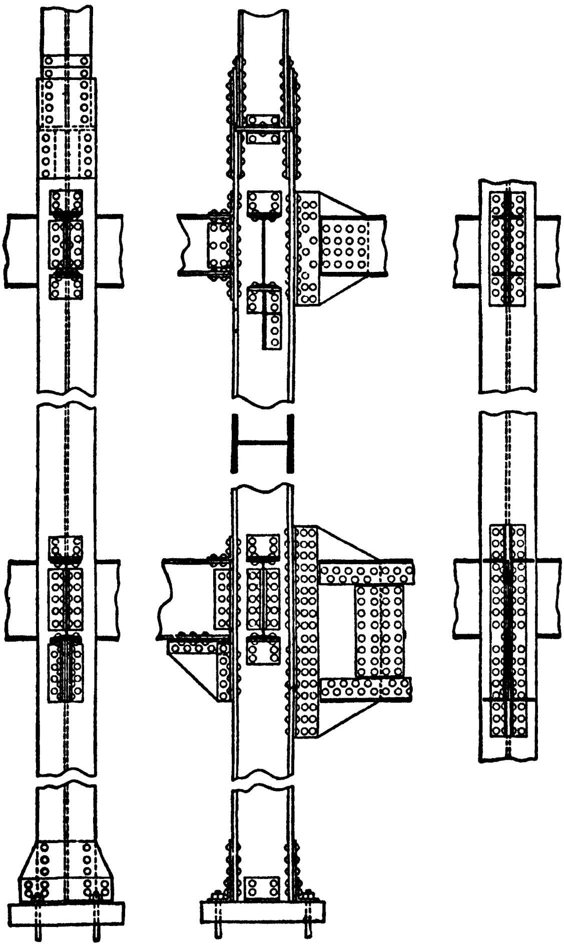

Fig. 1. Typical Bethlehem H Column Wind-Bracing Connections

D_A, D_B, D_C, D_D, etc. = direct stresses in the girders in the corresponding spans A, B, C, D, etc., pounds.

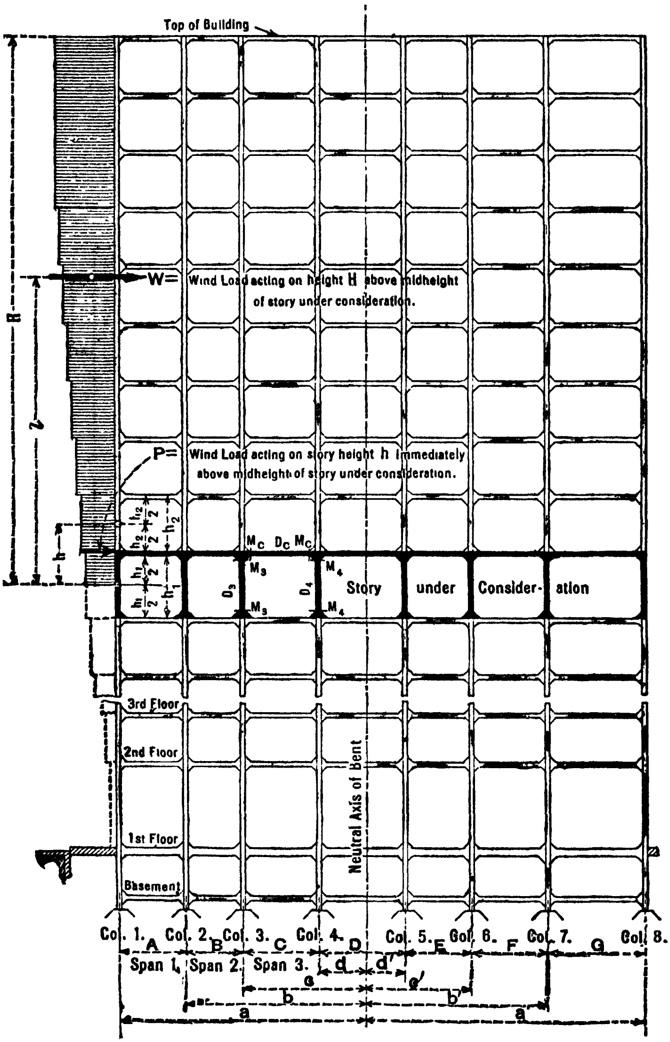

Fig. 2. Wind-Stresses in Buildings

The direct stresses and bending moments due to wind are given in the formulas and tables on the following pages.*

1. Unsymmetrical Building Bent. Varying or Uniform Wind-pressure. Most building codes specify a uniform wind-pressure for the full height of a building, but those of some cities, like Philadelphia and Boston, specify wind-pressures the magnitudes of which increase upwardly from a certain elevation.

The general formulas given below will apply in any case, but their use will be greatly simplified if the wind-pressure is uniform, as generally specified. For uniform wind-pressure the lever arm, l, of the wind-load W becomes equal to half the height H.

In order to find the bending moments and direct stresses due to the wind-load, proceed as follows:

(1) Locate the position of the neutral axis of the bent, so that

$$a + b + c + d + \ldots\ldots\ldots\ldots = a' + b' + c' + d' + \ldots\ldots\ldots\ldots$$

then calculate the quantity Q:

$$Q = (a)^2 + (a')^2 + (b)^2 + (b')^2 + (c)^2 + (c')^2 + (d)^2 + (d')^2 + \ldots\ldots$$

(2) Calculate, for the floor under consideration, the constant factors p, q, r and t.

$$p = \frac{2\,Wh - Ph_2}{4\,Q}, \qquad q = \frac{Wh_1}{2\,Wh - Ph_2}, \qquad r = \frac{Wl}{Q}, \qquad t = \frac{2\,P}{Wh_1}.$$

$$q' = \frac{W}{2\,W - P} \quad \left\{ \begin{array}{l} \text{Where the difference between } h_1 \\ \text{and } h_2 \text{ is negligible.} \end{array} \right.$$

(3) Find the moments at the ends of the girders, as follows:

$$\begin{aligned}
M_A &= pAa \\
M_B &= pB\,(a + b) \\
M_C &= pC\,(a + b + c) \\
M_D &= pD\,(a + b + c + d) = pD\,(a' + b' + c' + d') \\
M_E &= pE\,(a + b + c + d - d') = pE\,(a' + b' + c') \\
&\ldots\ldots\ldots
\end{aligned}$$

(4) Find the moments at the ends of the columns, as follows:

$$M_1 = qM_A \qquad M_2 = q\,(M_A + M_B) \qquad M_3 = q\,(M_B + M_C)$$
$$M_4 = q\,(M_C + M_D) \qquad M_5 = q\,(M_D + M_E)$$
$$\ldots\ldots\ldots$$

(5) Find the direct stresses in the columns, as follows:

$$D_1 = ra \qquad D_2 = rb \qquad D_3 = rc \qquad D_4 = rd \qquad D_5 = rd'$$
$$\ldots\ldots\ldots$$

(6) Find the direct stresses in the girders, as follows

$$D_A = P - tM_1 \qquad D_B = D_A - tM_2 \qquad D_C = D_B = tM_3$$
$$D_D = D_C - tM_4 \qquad D_E = D_D - tM_5$$
$$\ldots\ldots\ldots$$

The direct stresses in the columns are tensile (+) on the windward side and compressive (−) on the leeward side of the neutral axis of the building bent.

The direct stresses in the girders are compressive stresses. In stories for which P is the same, the direct stresses in corresponding girders are generally the same.

* "Tables and Formulas for Wind Stresses in Office Buildings," Engineering News-Record, Sept. 28, 1922.

2. Building Bent with Equal Spans, L. Uniform Wind-Pressure.
Note: The wind load below the story under consideration does not affect the calculations and need not be uniform. If the story under consideration is below ground-level, where all or part of $P = O$, use the formulas for varying wind-pressure.

In order to find the bending moments and direct stresses due to the wind-load, proceed as follows:

(1) Find the moments at the ends of the girders, taking the coefficients K_1 from the table below.

$$M = K_1 P\,(2\,H - h_2)$$

Number of spans in bent	Values of coefficients K_1									
	Span 1	Span 2	Span 3	Span 4	Span 5	Span 6	Span 7	Span 8	Span 9	Span 10
1	1/4									
2	1/8	1/8

10	215/220	201/220	180/220	154/220	125/220	95/220	66/220	40/220	19/220	5/220

The direct stresses in the girders are compressive stresses. In stories for which P is the same, the direct stresses in corresponding girders are the same.

Building Bent with Equal Spans, L. Uniform Wind-Pressure. Example. The direct wind-stresses in the columns and girders and the bending moments at their ends are required for a building bent. The building consists of 20 stories and a pent-house above ground, and a basement and sub-basement below, and is subjected to a wind-load of 15 lb per sq ft of exposed surface. The building bents, each consisting of three equal spans, L, between columns, are spaced 18 ft apart. The story heights are shown in the table below.

For all floors above ground the formulas and coefficients given in the tables under "2. Building Bent with Equal Spans, L. Uniform Wind-Pressure" are applicable. For the basement and sub-basement the basic formulas under "1. Unsymmetrical Building Bent. Varying or Uniform Wind-Pressure" have been used.

The exposed area for any story equals the product of the average story height, h, by the distance center to center of bays. The wind load, P, at each floor is obtained by multiplying the exposed area by the unit wind-pressure; hence $P = 18 \times h \times 15 = 270\,h$. The total wind-load, W, is obtained by adding the values of P, down to and including the story under consideration.

HORSE-POWER, PULLEYS, GEARS, BELTING AND SHAFTING

Horse-Power. A horse can travel 400 yd at a walk in 4½ min, at a trot in 2 min, and at a gallop in 1 min; he occupies at a picket 3 ft by 9 ft; and his average weight is 1 000 lb. An AVERAGE HORSE carrying 225 lb can travel 25 miles in a day of 8 hr. A DRAUGHT-HORSE can draw 1 600 lb 23 miles a day, weight of carriage included. In a HORSE-MILL a horse moves at the rate of 3 ft in a second. The diameter of the track should not be less than 25 ft.

A Horse-Power, in Machinery, is estimated at 33 000 lb, raised 1 ft in a minute; but as a horse can exert that force but 6 hr a day, one MACHINERY HORSE-POWER is equivalent to that of four hourses.

Rules to Determine the Size and Speed of Pulleys or Gears. The driving-pulley is called the DRIVER, and the driven pulley the DRIVEN. If the number of teeth in the gears are used instead of the diameter, in these calculations, number of teeth must be substituted wherever diameter occurs.

(1) **To Find the Diameter of the Driver,** the diameter of the driven and its revolutions, and also revolutions of driver, being given. Multiply the diameter of the driven by its revolutions, and divide the product by the revolutions of the driver; the quotient will give the diameter of the driver.

(2) **To Find the Diameter of the Driven,** the revolutions of the driven, also the diameter and revolutions of the driver, being given. Multiply the diameter of the driver by its revolutions, and divide the product by the revolutions of the driven; the quotient will give the diameter of the driven.

(3) **To Find the Revolutions of the Driver,** the diameter and revolutions of the driven, also the diameter of the driver, being given. Multiply the diameeter of the driven by its revolutions, and divide the product by the diameter of the driver; the quotient will give the revolutions of the driver.

(4) **To Find the Revolutions of the Driven,** the diameter and revolutions of the driver, also the diameter of the driven, being given Multiply the diameter of the driver by its revolutions, and divide the product by the diameter of the driven; the quotient will give the revolutions of the driven.

Horse-Power Transmitted by Belting. The efficiency of belting to transmit power, or to turn a wheel or PULLEY, depends upon the width and thickness of the belt, the arc-contact with the pulley, the position of the belt, whether horizontal, vertical, or at an angle, and the velocity. The greater the velocity and the thicker or wider the belt, the more power it will transmit. A belt running vertically or inclined will transmit less power than one running horizontally, but in figuring the horse-power capacity of belting only the velocity, width and thickness of belt are usually considered, it being assumed that the pulleys are of proper size and located so that the belt will be nearly horizontal. Belts are commonly assumed to be of LEATHER, unless otherwise designated. The term SINGLE BELT is used to designate a belt made of a single thickness of leather. A DOUBLE BELT or a TRIPLE BELT is made by cementing together two or three thicknesses of leather. The standard average thickness of single belts are ⅛, 5/32 and 3/16 in, and the standard average thicknesses of double belts are ¼, 5/16 and ⅜ in.

Notes on Belting. For continuous use a double belt is the most economical in the long run, except on very small pulleys or for very light duty. Triplex and quadruple belts are sometimes used for very heavy duty, but such belts are not commonly carried in stock. Single belts should always be used with the

hair-side next the pulley. The belt-speed for maximum economy should be from 4 000 to 4 500 ft per minute. IDLER-PULLEYS work most satisfactorily when located on the slack side of the belt about one-quarter way from the driving-pulley.

The best method of installing a leather belt is to splice and cement the ends together, and this method should always be used for electric motor or generator installations as well as for all wide belts or heavy drives. For all other cases the ends may be fastened with hooks or lacing. Belts should be inspected at regular intervals and given any necessary attention or repairs.

Distance from Center to Center of Shafts.* In locating shafts that are to be connected with each other by belts, care should be taken to separate them by a proper distance. This distance should be such as to allow a gentle sag to the belt when in motion.

Rule. A general rule may be stated thus: Where narrow belts are to be run over small pulleys, 15 ft is a good average, the belt having a sag of from 1½ to 2 in. The minimum distance between shafts is about 10 ft. For larger belts, working on larger pulleys, a distance of from 20 to 25 ft does well, with a sag of from 2½ to 4 in. For main belts, working on very large pulleys, the distance should be from 25 to 30 ft, the belts working well with a sag of from 4 to 5 in. If too great a distance is attempted, the belt will have an unsteady flapping motion, which will destroy both the belt and the machinery.

The Horse-Power that Shafting will Transmit

Arrangement of Belts and Pulleys.† If possible to avoid it, connected shafts should never be placed one directly over the other, as in such case the belt must be kept very tight to do the work. For this purpose belts should be

* For a discussion of belting, belt-dressing, care of belting, shafting, etc., see Kent's Mechanical Engineers' Pocket-Book.

† See Kent's Mechanical Engineers' Pocket-Book.

carefully selected of well-stretched leather. It is desirable that the angle of the belt with the floor should not exceed 45°. It is also desirable to locate the shafting and machinery so that belts will run off from each shaft in opposite directions, as this arrangement will relieve the bearings from the friction that would result if all pulled one way on the shaft. If possible, machinery should be so placed that the direction of the belt-motion will be from the top of the driving to the top of the driven pulley, so that the sag will increase the arc of contact. The pulley should be a little wider than the belt required for the work, and should have a crowning face, except where the belt is to be shifted. The motion of driving should run with and not against the laps of the belts.

Rubber Belts are cheaper than leather belts but they are not as durable. They should always be kept free from grease or animal oils. If they slip, their inside surfaces should be moistened with boiled linseed-oil. Some fine chalk, sprinkled on over the oil, will help the belt.

Rule for Finding the Lengths of Belts. Add the diameter of the two pulleys together, multiply by $3\frac{1}{7}$, divide the product by 2, add to the quotient twice the distance between the center of the shafts, and the sum will be the required length when the pulleys are of equal diameter.

CHAIN-BLOCKS, HOISTS, HOOKS, ETC.

General Description. These are portable hoisting-devices which enable one man to raise a very heavy load and which sustain the load at any point. In general, they resemble pulleys operated by chains. Since the invention of the differential pulley-block by T. A. Weston, about the year 1863, chain-blocks have come into very general use for economical hoisting, particularly where it is desired to hold the load at any point. Chain-blocks are of three general classes:

(1) The Differential Block. This is the original and the simplest and cheapest form of self-sustaining pulley;

(2) The Screw-Block or Worm-Geared Block. Of these, the Yale & Towne duplex block is an efficient type;

(3) The Triplex Block. This is spur-geared.

Differential and worm-geared blocks of all kinds depend upon friction to prevent the load from running down. In the triplex block a separate device is introduced which automatically holds the load safely, and yet enables it to be lowered with slight effort and at high velocity but without acceleration or danger. This is the most efficient of all chain-blocks, and the most economical wherever quick work is wanted and economy in time and labor sought. For information as to the kind of block best adapted to any particular service, the manufacturers should be consulted. The following data on the power and efficiency of chain-blocks were supplied by the Yale & Towne Manufacturing Company.

Power and Efficiency of Chain-Hoists. The table below gives the work to be done by the operator at the hand-pulling chain with each size of the various kinds of chain-blocks in lifting the stated capacity, that is, the amount of work or pulling required to lift this load ONE FOOT by stating the force exerted in pounds and the distance in feet of operating-chains to be pulled. The product of these two factors determines the efficiency of the block and the ease and speed of hoisting. The 12, 16, and 20-ton-capacity chain-blocks have each two hand-chains.

Work Done by Operator with Chain-Blocks

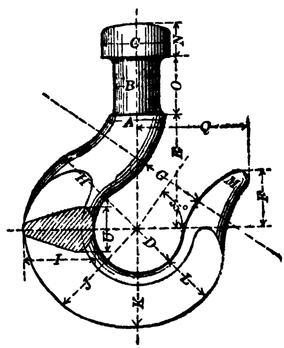
8	135 × 168	160 × 310	.
10	140 × 210	160 × 390	.
12	130 × 126	.	. .
16	135 × 168		.
20	140 × 210		.

The capacities are given in tons. The figures give the number of feet to be operated on each hand-chain. A man cannot pull more than his own weight on the operating chains, and can pull faster in proportion as the pull required is lighter. The maximum pull usually required of one man is 82 lb, and he will do more work with less fatigue if the hand-chain pull is not over 40 lb, because he can then pull the chain hand over hand a little more than twice as fast as he could when pulling twice as hard. When the hand-chain pull is less than 20 lb the speed of hoisting an equal load is diminished, because the man is tired by moving his arms too rapidly, and cannot do as much work as with a heavier pull. The best result is obtained by using a chain-block which has a capacity of double the usual load. The operator then works to the best advantage with average loads, and occasional heavy loads are easily handled without overstraining either the operator or the chain-block, which should never be used beyond its capacity for fear of stretching the chain so that it will not work smoothly.



Proportions of Hooks.* For economy of manufacture hooks of different sizes are made from some regular commercial sizes of round iron. The basis, or initial point, in each case is, therefore, the size of the iron of which the hook is to be made, and it is indicated by the dimension A in the diagram. The dimension D is arbitrarily assumed. The other dimensions, as given by the formulas, are those which, while preserving a proper bearing face on the interior of the hook for the ropes or chains which may be passed through it, give the greatest resistance to spreading and to ultimate rupture which the amount of material in the original bar admits of.

* By Henry R. Towne, in his Treatise on Cranes, which includes the results of an extensive experimental and mathematical investigation.

The symbol Δ is used in the formulas to indicate the NOMINAL CAPACITY of the hook in tons of 2 000 lb. The formulas which determine the lines of the other parts of the hooks of the several sizes are as follows, all the measurements being expressed in inches:

$D = 0.5\ \Delta + 1.25$	$G = 0.75\ D$
$E = 0.64\ \Delta + 1.60$	$O = 0.363\ \Delta + 0.66$
$F = 0.33\ \Delta + 0.85$	$Q = 0.64\ \Delta + 1.60$
$H = 1.08\ A$	$L = 1.05\ A$
$I = 1.33\ A$	$M = 0.50\ A$
$J = 1.20\ A$	$N = 0.85\ B - 0.16$
$K = 1.13\ A$	$U = 0.866\ A$

Example. To find the dimension D, for a 2-ton hook. The formula is:

$$D = 0.5\ \Delta + 1.25$$

and as $\Delta = 2$, the dimension D by the formula is found to be $2\frac{1}{4}$ in. The dimensions A are necessarily based upon the ordinary merchant sizes of round iron. The sizes which it has been found best to select are the following:

Capacities of hooks	$\frac{1}{8}$	$\frac{1}{4}$	$\frac{1}{2}$	1	$1\frac{1}{2}$	2	3	4	5	6	8	10 tons
Dimension A....	$\frac{5}{8}$	$\frac{11}{16}$	$\frac{3}{4}$	$1\frac{1}{16}$	$1\frac{1}{4}$	$1\frac{3}{8}$	$1\frac{3}{4}$	2	$2\frac{1}{4}$	$2\frac{1}{2}$	$2\frac{7}{8}$	$3\frac{1}{4}$ in

The formulas which give the sections of the hook at the several points are all expressed in terms of A, and can therefore be readily ascertained by reference to the foregoing scale.

Example. To find the dimension I, in a 2-ton hook. The formula is:

$$I = 1.33\ A$$

and for a 2-ton hook, $A = 1\frac{3}{8}$ in. Therefore I, in a 2-ton hook, is found to be $1\frac{13}{16}$ in.

Manner of Failure of Hooks. Experiment has shown that hooks made according to the above formulas will give way first by the opening of the jaw, which, however, will not occur except with a load much in excess of the nominal capacity of the hook. This yielding of the hook when overloaded becomes a source of safety, as it constitutes a signal of danger which cannot easily be overlooked, and which must proceed to a considerable length before rupture occurs and the load is dropped. A comparison of these hooks with most of those in ordinary use shows that the latter are, as a rule, badly proportioned, and frequently dangerously weak.

SYMBOLS FOR THE APOSTLES AND SAINTS

From the constant occurrence of symbols in the edifices of the Middle Ages and many of the cathedrals of the present day, the following list of symbols, as commonly attached to the apostles and saints, may be found useful:

Holy Apostles

St. Peter. Bears a key, or two keys with different wards.
St. Andrew. Leans on a cross so called from him; called by heralds the saltire.
St. John the Evangelist. With a chalice, in which is a winged serpent. When this symbol is used, the eagle, another symbol of him, is never given.
St. Bartholomew. With a flaying-knife.
St. James the Less. A fuller's staff bearing a small square banner.
St. James the Greater. A pilgrim's staff, hat and escalop-shell.
St. Thomas. An arrow, or with a long staff.
St. Simon. A long saw.
St. Jude. A club.
St. Matthias. A hatchet.
St. Philip. Leans on a spear or has a long cross in the shape of a **T**.
St. Matthew. A knife or dagger.
St. Mark. A winged lion.
St. Luke. A bull.
St. John. An eagle.
St. Paul. An elevated sword, or two swords in saltire.
St. John the Baptist. An Agnus Dei.
St. Stephen. With stones in his lap.

Saints

St. Agnes. A lamb at her feet.
St. Cecilia. With an organ.
St. Clement. With an anchor.
St. David. Preaching on a hill.
St. Denis. With his head in his hands.
St. George. With the dragon
St. Nicholas With three naked children in a tub, in the end whereof rests his pastoral staff.
St. Vincent. On the rack.

THE AMERICAN INSTITUTE OF ARCHITECTS

1. DOCUMENTS OF A PERMANENT NATURE—TITLES AND PRICES

The following documents are published by the American Institute of Architects, The Octagon, 1741 New York Ave , Washington, D. C., and may be obtained by addressing the Executive Secretary.

The Octagon, A Journal of The American Institute of Architects, Yearly	$ 1.00

Combined Filing System and Index	1.00

2. PROFESSIONAL PRACTICE OF ARCHITECTS *

Details of Service to be Rendered and Schedule of Proper Minimum Charges. Art. VI of the Constitution of The American Institute of Architects is as follows. The Institute shall from time to time adopt a Code or Codes, which shall be standards of professional practice, and it may from time to time recommend a Schedule of Professional Charges, complying with good practice and custom, but such a Schedule shall not be made mandatory.

1. The Architect's professional services consist of the necessary conferences, the preparation of preliminary studies, working drawings, specifications, large scale and full size detail drawings; the drafting of forms of proposals and contracts; the issuance of certificates of payment; the keeping of accounts, the general administration of the business and supervision of the work, for which, except as hereinafter mentioned, a proper minimum charge, based upon the total cost of the work complete, is 6%.

2. On residential work, alterations to existing buildings, monuments, furniture, decorative and cabinet work, and landscape architecture, it is proper to make a higher charge than above indicated.

3. The Architect is entitled to compensation for articles purchased under his direction, even though not designed by him.

4. Where the Architect is not otherwise retained, consultation fees for professional advice are to be paid in proportion to the importance of the question involved and services rendered.

5. The Architect is to be reimbursed the costs of transportation and living incurred by him and his assistants while traveling in discharge of duties connected with the work, and the costs of the services of heating, ventilating, mechanical, and electrical engineers.

6. The rate of percentage arising from Articles 1 and 2 hereof, i.e., the basic rate, applies when all of the work is let under one contract. Should the Owner determine to have certain portions of the work executed under separate contracts, as the Architect's burden of service, expense and responsibility is thereby increased, the rate in connection with such portions of the work is greater (usually by 4%) than the basic rate. Should the Owner determine to have substantially the entire work executed under separate contracts, then such higher rate applies to the entire work. In any event, however, the basic rate, without increase, applies to contracts for any portions of the work on which the Owner reimburses the engineer's fees to the Architect.

7. If, after a definite scheme has been approved, the Owner makes a decision which, for its proper execution, involves extra services and expense for changes in or additions to the drawings, specifications or other documents; or if a contract be let by cost of labor and materials plus a percentage or fixed sum; or if the Architect be put to labor or expense by delays caused by the Owner or a contractor, or by the delinquency or insolvency of either, or as a result of damage by fire or other casualty, he is to be equitably paid for such extra service and expense.

* The American Institute of Architects Document No. 177. Reprinted by permission.
The words "the cost of the work," as used in Articles 1 and 9 hereof, are ordinarily to be interpreted as meaning the total of the contract sums incurred for the execution of the work not including Architect's and Engineer's fees or the salary of the clerk of the works, but in certain rare cases, e g., when labor or material is furnished by the Owner below its market cost or when old materials are re-used, the cost of the work is to be interpreted as the cost of all materials and labor necessary to complete the work, as such cost would have been if all materials had been new and if all labor had been fully paid at market prices current when the work was ordered, plus contractor's profits and expenses

8. Should the execution of any work designed or specified by the Architect or any part of such work be abandoned or suspended, the Architect is to be paid in accordance with or in proportion to the terms of Article 9 of this Schedule for the service rendered, up to the time of such abandonment or such suspension.

9. Whether the work be executed or whether its execution be suspended or abandoned in part or whole, payments to the Architect on his fee are subject to the provisions of Articles 7 and 8, made as follows:

Upon completion of the preliminary studies, a sum equal to 20% of the basic rate computed upon a reasonable estimated cost.

Upon completion of specifications and general working drawings (exclusive of details) a sum sufficient to increase payments on the fee to 60% of the rate or rates of commission agreed upon, as influenced by Article 6, computed upon a reasonable cost estimated on such completed specifications and drawings, or if bids have been received, then computed upon the lowest bona fide bid or bids.

During the preparation of the preliminary studies and of the specifications and general working drawings, it is proper that payments on account be made at monthly or other intervals, in proportion to the progress of the architect's service, and so as to aggregate in each period not more than the sums described above.

From time to time during the execution of work and in proportion to the amount of service rendered by the Architect, payments are made until the aggregate of all payments made on account of the fee under this Article reaches a sum equal to the rate or rates of commission agreed upon as influenced by Article 6, computed upon the final cost of the work.

Payments to the Architect, other than those on his fee, fall due from time to time as his work is done or as costs are incurred.

No deduction is made from the Architect's fee on account of the use of old materials, penalty, liquidated damages or other sums withheld from payments to contractors.

10. The Owner is to furnish the Architect with a complete and accurate survey of the building site, giving the grades and lines of streets, pavements and adjoining properties; the rights, restrictions, easements, boundaries and contours of the building site, and full information as to sewer, water, gas and electrical service. The Owner is to pay for borings or test pits and for chemical, mechanical or other tests, when required.

11. The Architect endeavors to guard the Owner against defects and deficiencies in the work of contractors, but does not guarantee the performance of their contracts. The supervision of an architect is to be distinguished from the continuous personal superintendence to be obtained by the employment of a clerk of the works.

When authorized by the Owner, a clerk of the works, acceptable to both Owner and Architect, is to be engaged by the Architect at a salary satisfactory to the Owner and paid by the Owner, upon presentation of the Architect's monthly certificates.

12. When requested to do so, the Architect makes or procures preliminary estimates on the cost of the work and he endeavors to keep the actual cost of the work as low as may be consistent with the purpose of the building and with proper workmanship and material, but no such estimate can be regarded as other than an approximation.

13. Drawings and specifications, as instruments of service, are the property of the Architect, whether the work for which they are made be executed or not.

THE GENERAL CONDITIONS OF THE CONTRACT FOR THE CONSTRUCTION OF BUILDINGS *

STANDARD FORM OF THE AMERICAN INSTITUTE OF ARCHITECTS

These General Conditions have received the approval of the National Association of Builders' Exchanges, the Associated General Contractors of America, the Joint Conference on Construction Contracts, the National Association of Master Plumbers, the National Association of Sheet Metal Contractors of the United States, the National Electrical Contractors' Association of the United States, the National Association of Marble Dealers, the Building Granite Quarries Association, the Producers' Council and the Building Trades Employers' Association of the City of New York.

Index to the Articles of the General Conditions

Art. 1. Definitions.

(a) The Contract Documents consist of the Agreement, the General Conditions of the Contract, the Drawings and Specifications, including all modifications thereof incorporated in the documents before their execution. These form the Contract.

(b) The Owner, the Contractor and the Architect are those mentioned as such in the Agreement. They are treated throughout the Contract Documents as if each were of the singular number and masculine gender.

(c) The term Subcontractor, as employed herein, includes only those having a direct contract with the Contractor and it includes one who furnishes material worked to a special design according to the plans or specifications of

* Reprinted by permission.

this work, but does not include one who merely furnishes material not so worked.

(d) Written notice shall be deemed to have been duly served if delivered in person to the individual or to a member of the firm or to an officer of the corporation for whom it is intended, or if delivered at or sent by registered mail to the last business address known to him who gives the notice.

(e) The term "work" of the Contractor or Subcontractor includes labor or materials or both.

(f) All time limits stated in the Contract Documents are of the essence of the Contract.

(g) The law of the place of building shall govern the construction of this Contract.

Art. 2. Execution, Correlation and Intent of Documents. The Contract Documents shall be signed in duplicate by the Owner and the Contractor. In case the Owner and the Contractor fail to sign the General Conditions, Drawings or Specifications, the Architect shall identify them.

The Contract Documents are complementary, and what is called for by any one shall be as binding as if called for by all. The intention of the documents is to include all labor and materials, equipment and transportation necessary for the proper execution of the work. It is not intended, however, that materials or work not covered by or properly inferable from any heading, branch, class or trade of the specifications shall be supplied unless distinctly so noted on the drawings. Materials or work described in words which so applied have a well-known technical or trade meaning shall be held to refer to such recognized standards.

Art. 3. Detail Drawings and Instructions. The Architect shall furnish, with reasonable promptness, additional instructions, by means of drawings or otherwise, necessary for the proper execution of the work. All such drawings and instructions shall be consistent with the Contract Documents, true developments thereof, and reasonably inferable therefrom.

The work shall be executed in conformity therewith and the Contractor shall do no work without proper drawings and instructions.

The Contractor and the Architect, if either so requests, shall jointly prepare a schedule, subject to change from time to time in accordance with the progress of the work, fixing the dates at which the various detail drawings will be required, and the Architect shall furnish them in accordance with that schedule. Under like conditions, a schedule shall be prepared, fixing the dates for the submission of shop drawings, for the beginning of manufacture and installation of materials and for the completion of the various parts of the work.

Art. 4. Copies Furnished. Unless otherwise provided in the Contract Documents, the Architect will furnish to the Contractor, free of charge, all copies of drawings and specifications reasonably necessary for the execution of the work.

Art. 5. Shop Drawings. The Contractor shall submit with such promptness as to cause no delay in his own work or in that of any other Contractor, two copies of all shop or setting drawings and schedules required for the work of the various trades, and the Architect shall pass upon them with reasonable promptness. The Contractor shall make any corrections required by the Architect, file with him two corrected copies and furnish such other copies as may be needed. The Architect's approval of such drawings or schedules shall not relieve the Contractor from responsibility for deviations from draw-

ings or specifications, unless he has in writing called the Architect's attention to such deviations at the time of submission, nor shall it relieve him from responsibility for errors of any sort in shop drawings or schedules.

Art. 6. Drawings and Specifications on the Work. The Contractor shall keep one copy of all drawings and specifications on the work, in good order, available to the Architect and to his representatives.

Art. 7. Ownership of Drawings and Models. All drawings, specifications and copies thereof furnished by the Architect are his property. They are not to be used on other work and, with the exception of the signed Contract set, are to be returned to him on request, at the completion of the work. All models are the property of the Owner.

Art. 8. Samples. The Contractor shall furnish for approval all samples as directed. The work shall be in accordance with approved samples.

Art. 9. Materials, Appliances, Employes. Unless otherwise stipulated, the Contractor shall provide and pay for all materials, labor, water, tools, equipment, light, power, transportation and other facilities necessary for the execution and completion of the work.

Unless otherwise specified, all materials shall be new and both workmanship and materials shall be of good quality. The Contractor shall, if required, furnish satisfactory evidence as to the kind and quality of materials.

The Contractor shall at all times enforce strict discipline and good order among his employes, and shall not employ on the work any unfit person or any one not skilled in the work assigned to him.

Art. 10. Royalties and Patents. The Contractor shall pay all royalties and license fees. He shall defend all suits or claims for infringement of any patent rights and shall save the Owner harmless from loss on account thereof, except that the Owner shall be responsible for all such loss when a particular process or the product of a particular manufacturer or manufacturers is specified, but if the Contractor has information that the process or article specified is an infringement of a patent he shall be responsible for such loss unless he promptly gives such information to the Architect or Owner.

Art. 11. Surveys, Permits and Regulations. The Owner shall furnish all surveys unless otherwise specified. Permits and licenses of a temporary nature necessary for the prosecution of the work shall be secured and paid for by the Contractor. Permits, licenses and easements for permanent structures or permanent changes in existing facilities shall be secured and paid for by the Owner, unless otherwise specified.

The Contractor shall give all notices and comply with all laws, ordinances, rules and regulations bearing on the conduct of the work as drawn and specified. If the Contractor observes that the drawings and specifications are at variance therewith, he shall promptly notify the Architect in writing, and any necessary changes shall be adjusted as provided in the Contract for changes in the work. If the Contractor performs any work knowing it to be contrary to such laws, ordinances, rules and regulations, and without such notice to the Architect, he shall bear all costs arising therefrom.

Art. 12. Protection of Work and Property. The Contractor shall continuously maintain adequate protection of all his work from damage and shall protect the Owner's property from injury or loss arising in connection with this Contract. He shall make good any such damage, injury or loss, except such as may be directly due to errors in the Contract Documents or caused by agents or employes of the Owner. He shall adequately protect adjacent property as provided by law and the Contract Documents. He shall provide

and maintain all passageways, guard fences, lights and other facilities for protection required by public authority or local conditions.

In an emergency affecting the safety of life or of the work or of adjoining property, the Contractor, without special instruction or authorization from the Architect or Owner, is hereby permitted to act, at his discretion, to prevent such threatened loss or injury, and he shall so act, without appeal, if so instructed or authorized. Any compensation, claimed by the Contractor on account of emergency work, shall be determined by agreement or Arbitration.

Art. 13. Inspection of Work. The Architect and his representative shall at all times have access to the work wherever it is in preparation or progress and the Contractor shall provide proper facilities for such access and for inspection.

If the specifications, the Architect's instructions, laws, ordinances or any public authority require any work to be specially tested or approved, the Contractor shall give the Architect timely notice of its readiness for inspection, and if the inspection is by another authority than the Architect, of the date fixed for such inspection. Inspections by the Architect shall be promptly made, and where practicable at the source of supply. If any work should be covered up without approval or consent of the Architect, it must, if required by the Architect, be uncovered for examination at the Contractor's expense.

Re-examination of questioned work may be ordered by the Architect and if so ordered the work must be uncovered by the Contractor. If such work be found in accordance with the Contract Documents the Owner shall pay the cost of re-examination and replacement. If such work be found not in accordance with the Contract Documents the Contractor shall pay such cost, unless he shall show that the defect in the work was caused by another Contractor, and in that event the Owner shall pay such cost.

Art. 14. Superintendence: Supervision. The Contractor shall keep on his work, during its progress, a competent superintendent and any necessary assistants, all satisfactory to the Architect. The superintendent shall not be changed except with the consent of the Architect, unless the superintendent proves to be unsatisfactory to the Contractor and ceases to be in his employ. The superintendent shall represent the Contractor in his absence and all directions given to him shall be as binding as if given to the Contractor. Important directions shall be confirmed in writing to the Contractor. Other directions shall be so confirmed on written request in each case.

The Contractor shall give efficient supervision to the work, using his best skill and attention. He shall carefully study and compare all drawings, specifications and other instructions and shall at once report to the Architect any error, inconsistency or omission which he may discover, but he shall not be held responsible for their existence or discovery.

Art. 15. Changes in the Work. The Owner, without invalidating the Contract, may order extra work or make changes by altering, adding to or deducting from the work, the Contract Sum being adjusted accordingly. All such work shall be executed under the conditions of the original contract except that any claim for extension of time caused thereby shall be adjusted at the time of ordering such change.

In giving instructions, the Architect shall have authority to make minor changes in the work, not involving extra cost, and not inconsistent with the purposes of the building, but otherwise, except in an emergency endangering life or property, no extra work or change shall be made unless in pursuance of a written order from the Owner signed or countersigned by the Architect, or a written order from the Architect stating that the Owner has authorized

the extra work or change, and no claim for an addition to the contract sum shall be valid unless so ordered.

The value of any such extra work or change shall be determined in one or more of the following ways:

(a) By estimate and acceptance in a lump sum
(b) By unit prices named in the contract or subsequently agreed upon.
(c) By cost and percentage or by cost and a fixed fee

If none of the above methods is agreed upon, the Contractor, provided he receives an order as above, shall proceed with the work In such case and also under case (c), he shall keep and present in such form as the Architect may direct, a correct account of the net cost of labor and materials, together with vouchers. In any case, the Architect shall certify to the amount, including reasonable allowance for overhead and profit, due to the Contractor. Pending final determination of value, payments on account of changes shall be made on the Architect's certificate.

Art. 16. Claims for Extra Cost. If the Contractor claims that any instructions by drawings or otherwise involve extra cost under this contract, he shall give the Architect written notice thereof within a reasonable time after the receipt of such instructions, and in any event before proceeding to execute the work, except in emergency endangering life or property, and the procedure shall then be as provided for changes in the work. No such claim shall be valid unless so made.

Art. 17. Deductions for Uncorrected Work. If the Architect and Owner deem it inexpedient to correct work injured or done not in accordance with the Contract, an equitable deduction from the contract price shall be made therefor.

Art. 18. Delays and Extension of Time. If the Contractor be delayed at any time in the progress of the work by any act or neglect of the Owner or the Architect, or of any employe of either, or by any other Contractor employed by the Owner, or by changes ordered in the work, or by strikes, lockouts, fire, unusual delay in transportation, unavoidable casualties or any causes beyond the Contractor's control, or by delay authorized by the Architect pending arbitration, or by any cause which the Architect shall decide to justify the delay, then the time of completion shall be extended for such reasonable time as the Architect may decide

No such extention shall be made for delay occurring more than seven days before claim therefor is made in writing to the Architect. In the case of a continuing cause of delay, only one claim is necessary.

If no schedule or agreement stating the dates upon which drawings shall be furnished is made, then no claim for delay shall be allowed on account of failure to furnish drawings until two weeks after demand for such drawings and not then unless such claim be reasonable.

This article does not exclude the recovery of damages for delay by either party under other provisions in the contract documents

Art. 19. Correction of Work before Final Payment. The Contractor shall promptly remove from the premises all materials condemned by the Architect as failing to conform to the Contract, whether incorporated in the work or not, and the Contractor shall promptly replace and re-execute his own work in accordance with the Contract and without expense to the Owner and shall bear the expense of making good all work of other contractors destroyed or damaged by such removal or replacement.

If the Contractor does not remove such condemned work and materials

within a reasonable time, fixed by written notice, the Owner may remove them and may store the material at the expense of the Contractor. If the Contractor does not pay the expenses of such removal within ten days' time thereafter, the Owner may, upon ten days' written notice, sell such materials at auction or at private sale and shall account for the net proceeds thereof, after deducting all the costs and expenses that should have been borne by the Contractor.

Art. 20. Correction of Work after Final Payment. Neither the final certificate nor payment nor any provision in the Contract Documents shall relieve the Contractor of responsibility for faulty materials or workmanship and, unless otherwise specified, he shall remedy any defects due thereto and pay for any damage to other work, resulting therefrom, which shall appear within a period of one year from the date of substantial completion. The Owner shall give notice of observed defects with reasonable promptness. All questions arising under this article shall be decided by the Architect subject to arbitration.

Art. 21. The Owner's Right to Do Work. If the Contractor should neglect to prosecute the work properly or fail to perform any provision of this contract, the Owner, after three days' written notice to the Contractor may, without prejudice to any other remedy he may have, make good such deficiencies and may deduct the cost thereof from the payment then or thereafter due the Contractor provided, however, that the Architect shall approve both such action and the amount charged to the Contractor.

Art. 22. Owner's Right to Terminate Contract. If the Contractor should be adjudged a bankrupt, or if he should make a general assignment for the benefit of his creditors, or if a receiver should be appointed on account of his insolvency, or if he should persistently or repeatedly refuse or should fail, except in cases for which extension of time is provided, to supply enough properly skilled workmen or proper materials, or if he should fail to make prompt payment to subcontractors or for material or labor, or persistently disregard laws, ordinances or the instructions of the Architect, or otherwise be guilty of a substantial violation of any provision of the contract, then the Owner, upon the certificate of the Architect that sufficient cause exists to justify such action, may, without prejudice to any other right or remedy and after giving the Contractor seven days' written notice, terminate the employment of the Contractor and take possession of the premises and of all materials, tools and appliances thereon and finish the work by whatever method he may deem expedient: In such case the Contractor shall not be entitled to receive any further payment until the work is finished. If the unpaid balance of the contract price shall exceed the expense of finishing the work, including compensation for additional managerial and administrative services, such excess shall be paid to the Contractor. If such expense shall exceed such unpaid balance, the Contractor shall pay the difference to the Owner. The expense incurred by the Owner as herein provided, and the damage incurred through the Contractor's default, shall be certified by the Architect.

Art. 23. Contractor's Right to Stop Work or Terminate Contract. If the work should be stopped under an order of any court, or other public authority, for a period of three months, through no act or fault of the Contractor or of anyone employed by him, or if the Architect should fail to issue any certificate for payment within seven days after it is due, or if the Owner should fail to pay to the Contractor within seven days of its maturity and presentation, any sum certified by the Architect or awarded by arbitrators, then the Contractor may, upon seven days' written notice to the Owner and the Architect,

stop work or terminate this contract and recover from the Owner payment for all work executed and any loss sustained upon any plant or materials and reasonable profit and damages.

Art. 24. Applications for Payments. The Contractor shall submit to the Architect an application for each payment, and, if required, receipts or other vouchers, showing his payments for materials and labor, including payments to subcontractors as required by Art. 37.

If payments are made on valuation of work done, such application shall be submitted at least ten days before each payment falls due, and, if required, the Contractor shall, before the first application, submit to the Architect a schedule of values of the various parts of the work, including quantities, aggregating the total sum of the contract, divided so as to facilitate payments to subcontractors in accordance with Art. 37 (e), made out in such form as the Architect and the Contractor may agree upon, and, if required, supported by such evidence as to its correctness as the Architect may direct. This schedule, when approved by the Architect, shall be used as a basis for certificates of payment, unless it be found to be in error. In applying for payments, the Contractor shall submit a statement based upon this schedule, and, if required, itemized in such form and supported by such evidence as the Architect may direct, showing his right to the payment claimed.

If payments are made on account of materials delivered and suitably stored at the site but not incorporated in the work, they shall, if required by the Architect, be conditional upon submission by the Contractor of bills of sale or such other procedure as will establish the Owner's title to such material or otherwise adequately protect the Owner's interest.

Art. 25. Certificates of Payments. If the Contractor has made application as above, the Architect shall, not later than the date when each payment falls due, issue to the Contractor a certificate for such amount as he decides to be properly due.

No certificate issued nor payment made to the Contractor, nor partial or entire use or occupancy of the work by the Owner, shall be an acceptance of any work or materials not in accordance with this contract The making and acceptance of the final payment shall constitute a waiver of all claims by the Owner, other than those arising from unsettled liens, from faulty work appearing after final payment or from requirement of the specifications, and of all claims by the Contractor, except those previously made and still unsettled.

Should the Owner fail to pay the sum named in any certificate of the Architect or in any award by arbitration, upon demand when due, the Contractor shall receive, in addition to the sum named in the certificate, interest thereon at the legal rate in force at the place of building.

Art. 26. Payments Withheld. The Architect may withhold or, on account of subsequently discovered evidence, nullify the whole or a part of any certificate to such extent as may be necessary to protect the Owner from loss on account of:

(a) Defective work not remedied.

(b) Claims filed or reasonable evidence indicating probable filing of claims.

(c) Failure of the Contractor to make payments properly to subcontractors or for material or labor.

(d) A reasonable doubt that the contract can be completed for the balance then unpaid.

(e) Damage to another Contractor.

When the above grounds are removed payment shall be made for amounts withheld because of them.

Art. 27. Contractor's Liability Insurance. The Contractor shall maintain such insurance as will protect him from claims under workmen's compensation acts and from any other claims for damages for personal injury, including death, which may arise from operations under this Contract, whether such operations be by himself or by any subcontractor or anyone directly or indirectly employed by either of them. Certificates of such insurance shall be filed with the Owner, if he so require, and shall be subject to his approval for adequacy of protection.

Art. 28. Owner's Liability Insurance. The Owner shall be responsible for and at his option may maintain such insurance as will protect him from his contingent liability for damages for personal injury, including death, which may arise from operations under this contract.

Art. 29. Fire Insurance. The Owner shall effect and maintain fire insurance upon the entire structure on which the work of this contract is to be done and upon all materials, in or adjacent thereto and intended for use thereon, to at least 80% of the insurable value thereof The loss, if any, is to be made adjustable with and payable to the Owner as Trustee for whom it may concern.

All policies shall be open to inspection by the Contractor If the Owner fails to show them on request, or if he fails to effect or maintain insurance as above, the Contractor may insure his own interest and charge the cost thereof to the Owner. If the Contractor is damaged by failure of the Owner to maintain such insurance, he may recover as stipulated in the contract for recovery of damages.

If required in writing by any party in interest, the Owner as Trustee shall, upon the occurrence of loss, give bond for the proper performance of his duties. He shall deposit any money received from insurance in an account separate from all his other funds and he shall distribute it in accordance with such agreement as the parties in interest may reach, or under an award of arbitrators appointed, one by the Owner, another by joint action of the other parties in interest, all other procedure being as provided elsewhere in the contract for Arbitration. If after loss no special agreement is made, replacement of injured work shall be ordered and executed as provided for changes in the work.

The Trustee shall have power to adjust and settle any loss with the insurers unless one of the Contractors interested shall object in writing within three working days of the occurrence of loss, and thereupon arbitrators shall be chosen as above. The Trustees shall in that case make settlement with the insurers in accordance with the directions of such arbitrators, who shall also, if distribution by arbitration is required, direct such distribution.

Art. 30. Guaranty Bonds. The Owner shall have the right, prior to the signing of the Contract, to require the Contractor to furnish bond covering the faithful performance of the Contract and the payment of all obligations arising thereunder, in such form as the Owner may prescribe and with such sureties as he may approve. If such bond is required by instructions given previous to the submission of bids, the premium shall be paid by the Contractor; if subsequent thereto, it shall be paid by the Owner.

Art. 31. Damages. If either party to this Contract should suffer damage in any manner because of any wrongful act or neglect of the other party or of anyone employed by him, then he shall be reimbursed by the other party for such damage.

Claims under this clause shall be made in writing to the party liable within a reasonable time at the first observance of such damage and not later than the time of final payment except as expressly stipulated otherwise in the case of faulty work or materials, and shall be adjusted by agreement or arbitration.

Art. 32. Liens. Neither the final payment nor any part of the retained percentage shall become due until the Contractor, if required, shall deliver to the Owner a complete release of all liens arising out of this Contract, or receipts in full in lieu thereof and, if required in either case, an affidavit that so far as he has knowledge or information the releases and receipts include all the labor and material for which a lien could be filed, but the Contractor may, if any subcontractor refuses to furnish a release or receipt in full. furnish a bond satisfactory to the Owner, to indemnify him against any lien. If any lien remain unsatisfied after all payments are made, the Contractor shall refund to the Owner all moneys that the latter may be compelled to pay in discharging such a lien, including all costs and a reasonable attorney's fee

Art. 33. Assignment. Neither party to the Contract shall assign the Contract or sublet it as a whole without the written consent of the other, nor shall the Contractor assign any moneys due or to become due to him hereunder, without the previous written consent of the Owner.

Art. 34. Mutual Responsibility of Contractors. Should the Contractor cause damage to any other contractor on the work the Contractor agrees, upon due notice, to settle with such contractor by agreement or arbitration, if he will so settle. If such other contractor sues the Owner on account of any damage alleged to have been so sustained, the Owner shall notify the Contractor, who shall defend such proceedings at the Owner's expense and, if any judgment against the Owner arise therefrom, the Contractor shall pay or satisfy it and pay all costs incurred by the Owner.

Art. 35. Separate Contracts. The Owner reserves the right to let other contracts in connection with this work. The Contractor shall afford other contractors reasonable opportunity for the introduction and storage of their materials and the execution of their work, and shall properly connect and coordinate his work with theirs

If any part of the Contractor's work depends for proper execution or results upon the work of any other contractor, the Contractor shall inspect and promptly report to the Architect any defects in such work that render it unsuitable for such proper execution and results. His failure so to inspect and report shall constitute an acceptance of the other contractor's work as fit and proper for the reception of his work, except as to defects which may develop in the other contractor's work after the execution of his work.

To insure the proper execution of his subsequent work the Contractor shall measure work already in place and shall at once report to the Architect any discrepancy between the executed work and the drawings

Art. 36. Subcontracts. The Contractor shall, as soon as practicable after the signature of the contract, notify the Architect in writing of the names of subcontractors proposed for the principal parts of the work and for such others as the Architect may direct and shall not employ any that the Architect may within a reasonable time object to as incompetent or unfit.

If the Contractor has submitted before signing the contract a list of subcontractors and the change of any name on such list is required in writing by the Owner after signature of agreement, the contract price shall be increased or diminished by the difference in cost occasioned by such change.

The Architect shall, on request, furnish to any subcontractor, wherever practicable, evidence of the amounts certified on his account.

The Contractor agrees that he is as fully responsible to the Owner for the acts and omissions of his subcontractors and of persons either directly or indirectly employed by them, as he is for the acts and omissions of persons directly employed by him.

Nothing contained in the contract documents shall create any contractual relation between any subcontractor and the Owner.

Art. 37. Relations of Contractor and Subcontractor. The Contractor agrees to bind every Subcontractor and every Subcontractor agrees to be bound by the terms of the Agreement, the General Conditions, the Drawings and Specifications as far as applicable to his work, including the following provisions of this article, unless specifically noted to the contrary in a subcontract approved in writing as adequate by the Owner or Architect.

This does not apply to minor subcontracts

The Subcontractor agrees:

(a) To be bound to the Contractor by the terms of the Agreement, General Conditions, Drawings and Specifications, and to assume toward him all the obligations and responsibilities that he, by those documents, assumes toward the Owner.

(b) To submit to the Contractor applications for payment in such reasonable time as to enable the Contractor to apply for payment under Art. 24 of the General Conditions

(c) To make all claims for extras, for extensions of time and for damages for delays or otherwise, to the Contractor in the manner provided in the General Conditions for like claims by the Contractor upon the Owner, except that the time for making claims for extra cost is one week.

The Contractor agrees:

(d) To be bound to the Subcontractor by all the obligations that the Owner assumes to the Contractor under the Agreement, General Conditions, Drawings and Specifications, and by all the provisions thereof affording remedies and redress to the Contractor from the Owner

(e) To pay the Subcontractor, upon the issuance of certificates, if issued under the schedule of values described in Art. 24 of the General Conditions, the amount allowed to the Contractor on account of the Subcontractor's work to the extent of the Subcontractor's interest therein.

(f) To pay the Subcontractor, upon the issuance of certificates, if issued otherwise than as in (e), so that at all times his total payments shall be as large in proportion to the value of the work done by him as the total amount certified to the Contractor is to the value of the work done by him.

(g) To pay the Subcontractor to such extent as may be provided by the Contract Documents or the subcontract, if either of these provides for earlier or larger payments than the above.

(h) To pay the Subcontractor on demand for his work or materials as far as executed and fixed in place, less the retained percentage, at the time the certificate should issue, even though the Architect fails to issue it for any cause not the fault of the Subcontractor.

(j) To pay the Subcontractor a just share of any fire insurance money received by him, the Contractor, under Art. 29 of the General Conditions.

(k) To make no demand for liquidated damages or penalty for delay in any sum in excess of such amount as may be specifically named in the subcontract.

(l) That no claim for services rendered or materials furnished by the Contractor to the Subcontractor shall be valid unless written notice thereof is

given by the Contractor to the Subcontractor during the first ten days of the calendar month following that in which the claim originated.

(m) To give the Subcontractor an opportunity to be present and to submit evidence in any arbitration involving his rights.

(n) To name as arbitrator under arbitration proceedings as provided in the General Conditions the person nominated by the Subcontractor, if the sole cause of dispute is the work, materials, rights or responsibilities of the Subcontractor; or, if of the Subcontractor and any other subcontractor jointly, to name as such arbitrator the person upon whom they agree.

The Contractor and the Subcontractor agree that:

(o) In the matter of arbitration, their rights and obligations and all procedure shall be analogous to those set forth in this contract.

Nothing in this article shall create any obligation on the part of the Owner to pay to or to see to the payment of any sums to any Subcontractor

Art. 38. Architect's Status. The Architect shall have general supervision and direction of the work. He is the agent of the Owner only to the extent provided in the Contract Documents and when in special instances he is authorized by the Owner so to act, and in such instances he shall, upon request, show the Contractor written authority. He has authority to stop the work whenever such stoppage may be necessary to insure the proper execution of the Contract.

As the Architect is, in the first instance, the interpreter of the conditions of the Contract and the judge of its performance, he shall side neither with the Owner nor with the Contractor, but shall use his powers under the contract to enforce its faithful performance by both.

In case of the termination of the employment of the Architect, the Owner shall appoint a capable and reputable Architect, whose status under the contract shall be that of the former Architect.

Art. 39. Architect's Decisions. The Architect shall, within a reasonable time, make decisions on all claims of the Owner or Contractor and on all other matters relating to the execution and progress of the work or the interpretation of the Contract Documents.

The Architect's decisions, in matters relating to artistic effect, shall be final, if within the terms of the Contract Documents.

Except as above or as otherwise expressly provided in the Contract Documents, all the Architect's decisions are subject to arbitration.

Art. 40. Arbitration. All questions subject to arbitration under this Contract shall be submitted to arbitration at the choice of either party to the dispute.

The Contractor shall not cause a delay of the work during any arbitration proceedings, except by agreement with the Owner.

The demand for arbitration shall be filed in writing with the Architect, in the case of an appeal from his decision, within ten days of its receipt and in any other case within a reasonable time after cause thereof and in no case later than the time of final payment, except as otherwise expressly stipulated in the Contract. If the Architect fails to make a decision within a reasonable time, an appeal to arbitration may be taken as if his decision had been rendered against the party appealing.

No one shall be nominated or act as an arbitrator who is in any way financially interested in this Contract or in the business affairs of either the Owner, Contractor or Architect.

Unless otherwise provided by controlling statutes, the parties may agree

upon one arbitrator; otherwise there shall be three, one named in writing, by each party to this Contract, to the other party and to the Architect and the third chosen by these two arbitrators, or if they fail to select a third within fifteen days, then he shall be chosen by the presiding officer of the Bar Association nearest to the location of the work. Should the party demanding arbitration fail to name an arbitrator within ten days of his demand, his right to arbitration shall lapse. Should the other party fail to choose an arbitrator within said ten days, then such presiding officer shall appoint such arbitrator. Should either party refuse or neglect to supply the arbitrators with any papers or information demanded in writing, the arbitrators are empowered by both parties to proceed ex parte.

If there be one arbitrator his decision shall be binding; if three the decision of any two shall be binding. Such decision shall be a condition precedent to any right of legal action, and wherever permitted by law it may be filed in Court to carry it into effect.

The arbitrators, if they deem that the case demands it, are authorized to award to the party whose contention is sustained such sums as they shall deem proper for the time, expense and trouble incident to the appeal and, if the appeal was taken without reasonable cause, damages for delay. The arbitrators shall fix their own compensation, unless otherwise provided by agreement, and shall assess the costs and charges of the arbitration upon either or both parties.

The award of the arbitrators shall be in writing and it shall not be open to objection on account of the form of the proceeding or the award, unless otherwise provided by the controlling statutes

In the event of such statutes providing on any matter covered by this article otherwise than as hereinbefore specified, the method of procedure throughout and the legal effect of the award shall be wholly in accordance with the said statutes, it being intended hereby to lay down a principle of action to be followed, leaving its local application to be adapted to the legal requirements of the jurisdiction having authority over the arbitration.

Art. 41. Cash Allowances. The Contractor shall include in the contract sum of all allowances named in the Contract Documents and shall cause the work so covered to be done by such contractors and for such sums as the Architect may direct, the contract sum being adjusted in conformity therewith. The Contractor declares that the contract sum includes such sums for expenses and profit on account of cash allowances as he deems proper. No demand for expenses or profit other than those included in the contract sum shall be allowed. The Contractor shall not be required to employ for any such work persons against whom he has a reasonable objection.

Art. 42. Uses of Premises. The Contractor shall confine his apparatus, the storage of materials and the operations of his workmen to limits indicated by law, ordinances, permits or directions of the Architect and shall not unreasonably encumber the premises with his materials.

The Contractor shall not load or permit any part of the structure to be loaded with a weight that will endanger its safety.

The Contractor shall enforce the Architect's instructions regarding signs, advertisements, fires and smoking.

Art. 43. Cutting, Patching and Digging. The Contractor shall do all cutting, fitting or patching of his work that may be required to make its several parts come together properly and fit it to receive or be received by work of other contractors shown upon, or reasonably implied by, the Drawings and

Specifications for the completed structure, and he shall make good after them as the Architect may direct.

Any cost caused by defective or ill-timed work shall be borne by the party responsible therefor.

The Contractor shall not endanger any work by cutting, digging or otherwise, and shall not cut or alter the work of any other contractor save with the consent of the Architect.

Art. 44. Cleaning Up. The Contractor shall at all times keep the premises free from accumulations of waste material or rubbish caused by his employes or work, and at the completion of the work he shall remove all his rubbish from and about the building and all his tools, scaffolding and surplus materials and shall leave his work "broom clean" or its equivalent, unless more exactly specified. In case of dispute the Owner may remove the rubbish and charge the cost to the several contractors as the Architect shall determine to be just.

4. THE STANDARD FORM OF AGREEMENT BETWEEN CONTRACTOR AND OWNER FOR CONSTRUCTION OF BUILDINGS*

ISSUED BY THE AMERICAN INSTITUTE OF ARCHITECTS FOR USE WHEN A STIPULATED SUM FORMS THE BASIS OF PAYMENT

This form of agreement has received the approval of the National Association of Builders' Exchanges, the Associated General Contractors of America, the Joint Conference on Construction Contracts, the National Association of Master Plumbers, the National Association of Sheet Metal Contractors of the United States, the National Electrical Contractors' Association of the United States, the National Association of Marble Dealers, the Building Granite Quarries Association, the Producers' Council and the Building Trades Employers' Association of the City of New York.

 THIS FORM IS TO BE USED ONLY WITH THE STANDARD GENERAL CONDITIONS OF THE CONTRACT FOR CONSTRUCTION OF BUILDINGS

THIS AGREEMENT, made the.......................... ....day of
. . . . in the year Nineteen Hundred and ....
by and between . . ..
hereinafter called the Contractor, and ....
. . . .hereinafter called the Owner, ...

WITNESSETH, that the Contractor and the Owner for the considerations hereinafter named agree as follows:

Article 1. Scope of the Work. The Contractor shall furnish all of the materials and perform all of the work shown on the Drawings and described in the Specifications entitled........................ . . . .

(Here insert the caption descriptive of the work as used on the Drawings and in the other Contract Documents)

prepared by. ....
acting as and in these Contract Documents entitled the Architect; and shall do everything required by this Agreement, the General Conditions of the Contract, the Specifications and the Drawings.

* Reprinted by permission.

Article 2. Time of Completion. The work to be performed under this Contract shall be commenced ....
and shall be substantially completed.........·.. . ...
(Here insert stipulation as to liquidated damages, if any.)
....(Blank lines)............ . ...

Article 3. The Contract Sum. The Owner shall pay the Contractor for the performance of the Contract, subject to additions and deductions provided therein, in current funds as follows:...... ... .
(State here the lump sum amount, unit prices, or both, as desired in individual cases.)
.... (Blank lines) ....

Where the quantities originally contemplated are so changed that application of the agreed unit price to the quantity of work performed is shown to create a hardship to the Owner or the Contractor, there shall be an equitable adjustment of the Contract to prevent such hardship.

Article 4. Progress Payments. The Owner shall make payments on account of the Contract as provided therein, as follows:
On or about the....................day of each month.. ....
per cent of the value, based on the Contract prices, of labor and materials incorporated in the work and of materials suitably stored at the site thereof up to the . ...day of that month, as estimated by the Architect, less the aggregate of previous payments; and upon substantial completion of the entire work, a sum sufficient to increase the total payments to .. .
per cent of the contract price . . . .
(Insert here any provision made for limiting or reducing the amount retained after the work reaches a certain stage of completion)
. . . .(Blank lines).............. .. ..

Article 5. Acceptance and Final Payment. Final payment shall be due..... days after substantial completion of the work provided the work be then fully completed and the Contract fully performed.

Upon receipt of written notice that the work is ready for final inspection and acceptance, the Architect shall promptly make such inspection, and when he finds the work acceptable under the Contract and the Contract fully performed he shall promptly issue a final certificate, over his own signature, stating that the work provided for in this Contract has been completed and is accepted by him under the terms and conditions thereof, and that the entire balance found to be due the Contractor, and noted in said final certificate, is due and payable.

Before issuance of final certificate the Contractor shall submit evidence satisfactory to the Architect that all payrolls, material bills, and other indebtedness connected with the work have been paid.

If after the work has been substantially completed, full completion thereof is materially delayed through no fault of the Contractor, and the Architect so certifies, the Owner shall, upon certificate of the Architect, and without terminating the Contract, make payment of the balance due for that portion of the work fully completed and accepted. Such payment shall be made under the terms and conditions governing final payment, except that it shall not constitute a waiver of claims.

Article 6. The Contract Documents. The General Conditions of the Contract, the Specifications and the Drawings, together with this Agreement, form the Contract, and they are as fully a part of the Contract as if hereto attached or herein repeated. The following is an enumeration of the Specifications and Drawings:
............................(Blank page)...............................

IN WITNESS WHEREOF the parties hereto have executed this Agreement, the day and year first above written.

5. ARCHITECTURAL COMPETITIONS

Object. The object of a competition is to enable the Owner to secure a choice of designs by different authors, and the hope of those holding a competition is that by appealing to the competitive spirit of the architects they will be inspired to produce designs of outstanding merit.

In order that the competitors may be encouraged to produce the best of which they are capable, there should be a fair agreement between the Owner and the competitors.

All competitions should be conducted in general conformity with the principles set forth in "Competition Code" of the American Institute of Architects. The Institute does not give its approval to a program unless it meets the following essential conditions:

(a) That there be a Professional Adviser.

(b) That there be a Jury of at least three members, one of whom is a practicing Architect.

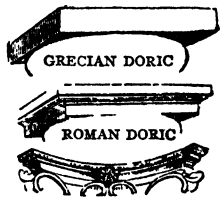
(c) That the program contain an Agreement and Conditions of Contract between Owner and Architect in accord with good practice.

GLOSSARY *

Technical Terms, Ancient and Modern, Used by Architects, Builders, and Draughtsmen

Aaron's-Rod. An ornamental figure representing a rod with a serpent twined about it. It is sometimes confounded with the caduceus of Mercury. The distinction between the caduceus and the Aaron's-rod is that the former has two serpents twined in opposite directions, whereas the latter has but one.

Abacus. The upper member of the capital of a column. It is sometimes square and sometimes curved, forming on the plan segments of a circle called the arch of the abacus, and is commonly decorated with a rose or other ornament in the center, having the angles, called horns of the abacus, cut off in the direction of the radius or curve. In the Tuscan or Doric, it is a square tablet; in the Ionic, the edges are molded; in the Corinthian, its sides are concave and frequently enriched with carving. In Gothic pillars it has a great variety of forms.



CORINTHIAN ABACUS

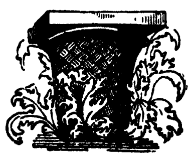
Abbey. A term for the church and other buildings used by conventual bodies presided over by an abbot or abbess, in contradistinction to cathedral, which is presided over by a bishop; and priory, the head of which was a prior or prioress.

Abutment. That part of a pier from which the arch springs.

Abuttals. The boundings of a piece of land on other land, street, river, etc.

Abyssinia, Architecture of. That of the ancient kingdom in northeast Africa. Evidences of Greek and, perhaps, of Egyptian culture have been found, but there seem to be only the remains of monuments erected by conquering chiefs. Portuguese influence in the fifteenth and sixteenth centuries has left some trace. It is evident that curious systems and devices, both in building and in ornamentation, are discoverable in this large, mountainous, and diversified country, containing a very ancient, though newer, high civilization.

Acanthus. A plant found in the south of Europe, representations of whose leaves are employed for decorating the Corinthian and Composite capitals. The leaves of the acanthus are used on the bell of the capital, and distinguish the two rich orders from the three others.



ACANTHUS

Acroteria. The small pedestals placed on the extremities and apex of a pediment. They are usually without bases or plinths, and were originally intended to receive statues.

Adobe. (1) An aluminous earth; (2) unfired brick made from such earth without fire; (3) with the article, a single brick of this kind; (4) a house built of these materials.

* This Glossary was compiled by Mr. Kidder from various sources. Excerpts, principally from "A Dictionary of Architecture and Building," by Russell C. Sturgis, have been added.

Aile, Aisle. The wings; inward side porticos of a church; the inward lateral corridors which enclose the choir, the presbytery, and the body of the church along its sides. Any one of the passages in a church or hall into which the pews or seats open.

Alcove. The original and strict meaning of this word, which is derived from the Spanish *alcoba*, is confined to that part of a bed-chamber in which the bed stands, separated from the other parts of the room by columns or pilasters. It is now commonly used to express any large recess in a room, generally separated by an arch.

Alipterion. In ancient Roman architecture, a room used by bathers for anointing themselves.

Alley. A narrow passageway: (1) between two houses, like a very narrow street; (2) in or under a house, as affording passage directly to the inner court or yard, without entering the rooms of the house; (3) a walk in a garden; (4) a long and narrow building.

Almonry. The place or chamber where alms were distributed to the poor in churches, or other ecclesiastical buildings. At Bishopstone Church, Wiltshire, England, it is a sort of covered porch attached to the south transept, but not communicating with the interior of the church. At Worcester Cathedral, England, the alms are said to have been distributed on stone tables, on each side, within the great porch. In large monastic establishments, as at Westminster, it seems to have been a separate building of some importance, either joining the gate-house or near it, that the establishment might be disturbed as little as possible.

Altar. In ancient Roman architecture, a place on which offerings or sacrifices were made to the gods. In Protestant churches, the communion table is often designated as the Altar, and in Roman Catholic churches it is a square table placed at the east end of the church for the celebration of mass.

Altar of Incense. A small table covered with plates of gold on which was placed the smoking censer in the temple at Jerusalem.

Altar-piece. The entire decorations of an altar; a painting placed behind an altar.

Altar-screen. The back of the altar from which the canopy was suspended, and separating the choir from the lady-chapel and presbytery. The altar-screen was generally of stone, and composed of the richest tabernacle work of niches, finials, and pedestals, supporting statues of the tutelary saints.

Alto-rilievo. High relief. A sculpture, the figures of which project from the surface on which they are carved.

Ambo. A raised platform, a pulpit, a reading-desk, a marble pulpit—an oblong enclosure in ancient churches, resembling in its uses and positions the modern choir.

Ambry. A cupboard or closet, frequently found near the altar in ancient churches to hold sacred utensils.

Ambulatory. An alley, a gallery, a cloister, a place for walking, as in a church or monastery.

Amerind Architecture; Amerindian Architecture. The architecture of the red races of America, the terms Amerind and Amerindian having been adopted by archæologists to replace the obviously inaccurate phrase "American Indian."

Amphiprostylos. A Grecian temple which has a columned portico on both ends.

Amphitheater. A double theater, of an elliptical form on the plan, for the exhibition of the ancient gladiatorial fights and other shows. Its arena or pit, in which those exhibitions took place, was encompassed with seats rising above each other, and the exterior had the accommodation of porticos or arcades for the public.

Amphora. A Grecian vase with two handles, often seen on medals.

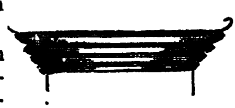
Ancones. The consoles or ornaments cut on the key-stones of arches or on the sides of door-cases. They are sometimes made use of to support busts or other figures.

Angle-capital. In Greek architecture, those Ionic capitals placed on the flank columns of a portico, which have one of their volutes placed horizontally at an angle of a hundred and thirty-five degrees with the plane of the frieze.

Annulated Columns. Columns clustered together by rings or bands; much used in English architecture.

Annular Vault. A vault rising from two parallel walls—the vault of a corridor. Same as *Barrel Vault.*

Annulet. A small square molding used to separate others. The fillet which separates the flutings of columns is sometimes known by this term.



ANNULET

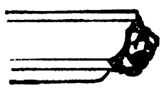
Anta, Antæ. A name given to a pilaster when attached to a wall. Vitruvius calls pilasters *parastatæ* when insulated. They are not usually diminished, and in all Greek examples their capitals are different from those of the columns they accompany.

Antechamber. An apartment preceded by a vestibule and from which another room is approached.

Antechapel. A small chapel forming the entrance to another. There are examples at Merton College, Oxford, and at King's College, Cambridge, England, besides several others. The antechapel to the lady-chapel in cathedrals is generally called the Presbytery.

Antechoir. The part under the rood loft, between the doors of the choir and the outer entrance of the screen, forming a sort of lobby. It is also called the Fore-choir.

Antefixa. In classical architecture (gargoyles, in Gothic architecture), the ornaments of lions' and other heads below the eaves of a temple, through channels in which, usually by the mouth, the water is carried from the eaves. By some this term is applied to the upright ornaments above the eaves in ancient architecture, which hid the ends of the Harmi or joint tiles.



ANTEFIXA

Apophyge. The lowest part of the shaft of an Ionic or Corinthian column, or the highest member of its base if the column be considered as a whole. The Apophyge is the inverted cavetto or concave sweep, on the upper edge of which the diminishing shaft rests.

Apron. A plain or molded piece of finish below the stool of a window, put on to cover the rough edge of the plastering.

Apse. The semicircular or polygonal termination to the chancel of a church. The term also applies to similar forms in other buildings.

Apteral. A temple without columns on the flanks or sides.

Aqueduct. An artificial canal for the conveyance of water, either above or under ground. The Roman aqueducts are mostly of the former construction.

Arabesque. A building after the manner of the Arabs. Ornaments used by the same people, in which no human or animal figures appear. Arabesque is sometimes improperly used to denote a species of ornaments composed of capricious fantastics and imaginary representations of animals and foliage so much employed by the Romans in the decorations of walls and ceilings.

ARABESQUE

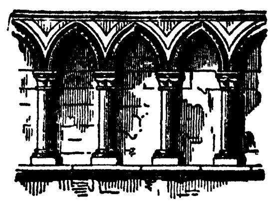
Arabian Architecture. A style of architecture the rudiments of which appear to have been taken from surrounding nations, the Egyptians, Syrians, Chaldeans, and Persians. The best preserved specimens partake chiefly of the Græco-Roman, Byzantine, and Egyptian. It is supposed that they constructed many of their finest buildings from the ruins of ancient cities

Aræostyle. That style of building in which the columns are distant from one another from four to five diameters. Strictly speaking, the term should be limited to intercolumniation of four diameters, which is only suited to the Tuscan order.

Aræosystylos. That style of building in which four columns are used in the space of eight diameters and a half; the central intercolumniation being three diameters and a half, and the others on each side being only half a diameter, by which arrangement coupled columns are introduced.

Arbores. Large bronze candelabra, in the shape of a tree, placed on the floor of ancient churches, so as to appear as if growing out of it.

Arcade. A range of arches, supported either on columns or on piers, and detached or attached to the wall.



ARCADE

Arch. In building, a mechanical arrangement of building materials arranged in the form of a curve, which preserves a given form when resisting pressure, and enables them, supported by piers or abutments, to carry weights and resist pressure.

Arch-buttress. Sometimes called a flying buttress; an arch springing from a buttress or pier.

Architect. A man charged with the preparation for a building, its plan and design, and with the supervision of the work of the builders who actually put it up and finish it. Literally, the term signifies nothing more than the head workman or director of the workmen, and the exact duties of the architect vary with the epoch, the country, the kind of building, and the wishes of the owner.

Architecture. The art of building in such a way as to accord with principles determined, not merely by the ends the edifice is intended to serve, but by high consideration of beauty and harmony. The aim of architecture as an art, is so to arrange the plan, masses and enrichments of a structure as to impart to it interest, beauty, grandeur, unity and power.

Architrave. That part of an entablature which rests upon the capital of a column, and is beneath the frieze.

Architrave Cornice. An entablature consisting of an architrave and cornice, without the intervention of the frieze, sometimes introduced when inconvenient to give the entablature the usual height.

Architrave of a Door. The finished work surrounding the aperture; the upper part of the lintel is called the traverse; and the sides, the jambs.

Archives. A repository or closet for the preservation of writings or records,

Archivolt. A collection of members forming the inner contour of an arch, or a band or frame adorned with moldings running over the faces or the arch-stones, and bearing upon the imposts.

Area. The superficial contents of any figure; an open space or court within a building; also, an uncovered space surrounding the foundation walls to give light to the basement.

Arena. The plain space in the middle of the amphitheater or other place of public resort.

Armory. (1) A room or building serving as a depository for arms and armor. (2) A building or establishment for the manufacture of arms, especially one maintained by the government. (3) A building for the use of a body of militia, with storage for their arms and equipments.

Arris. The meeting of two surfaces producing an angle.

Arsenal. (1) A public storehouse for arms and ammunition. (2) A place supported by government for manufacture of weapons. (3) Anciently, a government dock yard and navy yard.

Artificer, or **Artisan.** A person who works with his hands, and manufactures any commodity in iron, brass, wood, etc

Asarotum. In ancient architecture, a species of painted pavement used by the Romans before the invention of mosaic work.

Ashlar, or **Ashler.** A facing made of squared stones, or a facing made of thin slabs, used to cover walls of brick or rubble. *Coursed ashlar* is where the stones run in level courses all around the building; *random ashlar,* where the stones are of different heights, but level beds. Common freestones of small size, as they come from the quarry, are also called ashlar.

Asia Minor, Architecture of. Although Asia Minor formed a connecting passageway between the East and the West through which ebbed and flowed the art civilization from one to another, but little remains are found there from earlier than the fifth century B C. With few exceptions architectural developments are located on the seaboard. Here are found examples of Greek temples, Roman theaters, colonnaded streets, and tombs. The remains of the Byzantine Empire are comparatively few. The last architectural phase developed toward the end of the twelfth century under the Seljuk Sultans whose chief interest lies in the fact that it forms the foundation of the Turkish Saracenic style. The conical roofs with which all the Seljukian tombs are covered, in contradistinction to the domes which surmount all Persian and Cairene tombs, are probably derived from Armenian and Georgian prototypes.

Astragal. A small semicircular molding, sometimes plain and sometimes ornamented.

Asymptote. A straight line which continually approaches to a curve without touching it.

Atlases, or Atlantes. Figures or half-figures of men, used instead of columns or pilasters to support an entablature; called also Telamones.

Atrium. A court in the interior division of Roman houses.

Attached Columns. Those which project three-fourths of their diameter from the wall.

Attic. A low story above an entablature, or above a cornice which limits the height of the main part of an elevation. Although the term is evidently derived from the Greek, we find nothing exactly answering to it in Greek architecture; but it is very common in both Roman and Italian practice. What are otherwise called tholobates, in St. Peter's and St. Paul's Cathedrals are frequently termed Attics.

ATLANTES

Attic Order. A term used to denote the low pilasters employed in the decoration of an attic story.

Attributes. In painting and sculpture, symbols given to figures and statues to indicate their office and character.

Auditory. In ancient churches, that part of the church where the people usually stood to be instructed in the Gospel, now called the nave.

Aula. A court or hall in ancient Roman houses.

Australia, Architecture of. The natives of Australia were few in number when the land was first explored by Europeans, and were of a low type of savagery. The settlers of European stock have built cities generally laid out on generous lines for future development. The buildings are mostly close copies of modern English architecture of the more conventional and less interesting type. The more important buildings are of the neoclassic style, and cathedrals and university groups are artistic structures.

Austrian States, Architecture of. This presents fewer examples of mediæval architecture, especially churches, than any other German lands. Nature seems to have conspired against Austrian architecture; scarcely a building has escaped earthquake, tempest, or fire. The Cathedral at Vienna represents a valuable example of the beautiful Danubian architecture of the thirteenth century, also the remaining portions of the abbeys.

Aviary. A large apartment for breeding birds.

Axis. The spindle or center of any rotative motion. In a sphere, an imaginary line through the center.

Aztec Architecture. The architecture of the Nahuatl or Aztec tribes of Mexico. Popularly applied to all pre-Columbian Mexican architecture.

Back-choir. A place behind the altar in the principal choir, in which there is, or was, a small altar standing back to back with the former.

Backing of a Rafter or Rib. The forming of an upper or outer surface that it may range with the edges of the ribs or rafters on either side.

Backing of a Wall. The rough inner face of a wall; earth deposited behind a retaining wall, etc.

Back of a Window. That piece of wainscoting which is between the bottom of the sash frame and the floor.

Balcony. A projection from the face of a wall, supported by columns or consoles, and usually surrounded by a balustrade.

Baldachin. A building in the form of a canopy, supported with columns, and serving as a crown or covering to an altar.

Balloon Framing. In the United States a system of framing wooden buildings in which the corner posts and studs are continuous in one piece from sill to roof plate, the intermediate joists being carried by girts spiked to, or let into, the studs, the pieces being secured only by nailing, without the use of mortises and tenons, or the like.

BALDACHIN

Baluster. A small pillar or column, supporting a rail, of various forms, used in balustrades.

Baluster Shaft. The shaft dividing a window in Saxon architecture. At St. Albans are some of these shafts, evidently out of the old Saxon church, which have been fixed up with Norman capitals.

Balustrade. A series of balusters connected by a rail.

Band. A sort of flat frieze or fascia running horizontally round a tower or other parts of a building, particularly the base tables in perpendicular work, commonly used with the long shafts characteristic of the thirteenth century. It generally has a bold, projecting molding above and below, and is carved sometimes with foliages, but in general with cusped circles, or quatrefoils, in which frequently are shields of arms.

Band of a Column. A series of annulets and hollows going round the middle of the shafts of columns, and sometimes of the entire pier. They are often beautifully carved with foliages, etc., as at Amiens. In several cathedrals there are rings of bronze apparently covering the junction of the frusta of the columns. At Worcester and Westminster they appear to have been gilt; they are there more properly called Shaft-rings.

Baptistery. A separate building to contain the font, for the rite of baptism. Baptisteries are frequent on the Continent; that at Rome, near St. John Lateran, and those at Florence, Pisa, Pavia, etc., are all well-known examples. The only examples in England are at Cranbrook and Canterbury; the latter, however, is supposed to have been originally part of the treasury.

Barbican. An outwork for the defence of a gate or drawbridge; also, a sort of pent-house or construction of timber to shelter warders or sentries from arrows or other missiles.

Barge Board. See *Verge Board*.

Bartizan. A small turret, corbeled out at the angle of a wall or tower, to protect a warder and enable him to see around him. It generally is furnished with oylets or arrow-slits.

BARTIZAN

Basement. The lower part of a building, usually in part below the grade of the lot or street.

Base Moldings. The moldings immediately above the plinth of a wall, pillar, or pedestal.

Base of a Column. That part which is between the shaft and the pedestal or, if there be no pedestal, between the shaft and the plinth. The Grecian Doric had no base, and the Tuscan has only a single torus, or a plinth.

Basilica. A term given by the Greeks and Romans to the public buildings devoted to judicial purposes.

Bas-relief. See *Basso-rilievo.*

Basse-cour. A court separated from the principal one, and destined for stables, etc.

Basso-rilievo, or Bas-relief. The representations of figures projected from a background without being detached from it. It is divided into three parts: Alto-rilievo, when the figure projects more than one-half; Mezzo-rilievo, that in which the figure projects one-half; and Basso-rilievo, when the projection of the figure is less than one-half, as in coins.

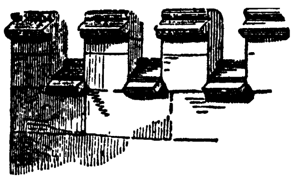
Bat. A part of a brick.

Batten. Small scantlings, or small strips of boards, used for various purposes. Small strips put over the joints of sheathing to keep out the weather.

Batten Door. A door made of sheathing, secured by strips of board, put crossways, and nailed with clinched nails.

Batter. A term used by bricklayers, carpenters, etc., to signify a wall, piece of timber, or other material, which does not stand upright, but inclines from you when you stand before it; but when, on the contrary, it leans toward you, it is said to overhang.

Battlement. A parapet with a series of notches in it, from which arrows may be shot, or other instruments of defence hurled on besiegers. The raised portions are called merlons; and the notches, embrasures or crenelles. The former were intended to cover the soldier while discharging his weapon through the latter. Their use is of great antiquity; they are found in the sculptures of Nineveh, in the tombs of Egypt, and on the famous François vase, where there is a delineation of the siege of Troy. In ecclesiastical architecture the early battlements have small shallow embrasures at some distance apart. In the Decorated period they are closer together, and deeper, and the moldings on the top of the merlon and bottom of the embrasure are richer. During this period, and the early part of the Perpendicular, the sides or cheeks of the embrasures are perfectly square and plain. In later times the moldings were continued round the sides, as well as at top and bottom, mitring at the angles, as over the doorway of Magdalen College, Oxford, England. The battlements of the Decorated and later periods are often richly ornamented by paneling, as in the last example. In castellated work the merlons are often pierced by narrow arrow-slits. (See *Oylet.*) In South Italy some battlements are found strongly resembling those of old Rome and Pompeii; in the Continental ecclesiastical architecture, the parapets are very rarely embattled.



BATTLEMENT

Bay. Any division or compartment of an arcade, roof, etc. Thus each space, from pillar to pillar, in a cathedral, is called a bay, or severy.

Bay-window. Any window projecting outward from the wall of a building, either square or polygonal on plan, and commencing from the ground. If they are carried on projecting corbels, they are called Oriel windows. Their use seems to have been confined to the later periods. In the Tudor and Elizabethan styles they are often semicircular in plan, in which case some think it more correct to call them Bow Windows.

Bazaar. A kind of Eastern mart, of Arabic origin.

Bead. A circular molding. When several are joined, it is called Reeding; when flush with the surface, it is called Quirk-bead; and when raised, Cock-bead.

Beam. A piece of timber, iron, stone, or other material, placed horizontally, or nearly so, to support a load over an opening, or from post to post.

Bearing. The portion of a beam, truss, etc., that rests on the supports.

Bearing Wall, or **Partition.** A wall which supports the floors and roofs in a building.

Beaufet, or **Buffet.** A small cupboard, or cabinet, to contain china. It may either be built into a wall, or be a separate piece of furniture.

Bed. In bricklaying and masonry, the horizontal surfaces on which the stones or bricks of walls lie in courses.

Bed of a Slate. The lower side.

Bed Moldings. Those moldings in all the orders between the corona and frieze.

Belfry. Properly speaking, a detached tower or campanile containing bells, as at Evesham, England, but more generally applied to the ringing-room or loft of the tower of a church. See *Tower*.

Belgium, Architecture of. The Architecture of Belgium is essentially Germanic in spirit, the style of detail, the disposition and character of buildings of all the periods showing the Teutonic origin of the people, though much of the mediæval work is inspired directly from France, the Renaissance reflects the influence of the Spanish domination and the modern buildings are almost wholly French by derivation. The most characteristic phase of the national architecture is that afforded by its civic buildings, which are in many respects unrivaled anywhere in the world. The Renaissance organ fronts also deserve study, notably in Louvain, Liège, and Brussels. In dignity of composition and masterly handling of mass the Brussels Palais de Justice is perhaps the most striking modern building of Europe.

Bell-cot, Bell-gable, or **Bell-turret.** The place where one or more bells are hung in chapels, or small churches which have no towers. Bell-cots are sometimes double, as at Northborough and Coxwell, England; a very common form in France and Switzerland admits of three bells. In these countries, also, they are frequently of wood, and attached to the ridge. Those which stand on the gable, dividing the nave from the chancel, are generally called Sanctus Bells. A very curious and, it is believed, unique example at Cleves Abbey, England, juts out from the wall. In later times bell-turrets were much ornamented; these are often called Flèches.

Bell of a Capital. In Gothic work, immediately above the necking is a deep, hollow curve; this is called the bell of a capital. It is often enriched with foliages. It is also applied to the body of the Corinthian and Composite capitals.

Belt. A course of stones or brick projecting from a brick or stone wall, generally placed in a line with the sills of the windows; it is either molded, fluted, plane, or enriched with patras at regular intervals. Sometimes called Stone String.

Belvedere, or **Look-out.** A turret or lantern raised above the roof of an observatory for the purpose of enjoying a fine prospect.

Bema. The semicircular recess, or exedra, in the basilica, where the judges sat, and where in aftertimes the altar was placed. It generally is roofed with a half-dome or concha. The seats of the priests were against the wall, looking into the body of the church, that of the bishop being in the center. The bema is generally ascended by steps, and railed off by cancelli.

Bench Table. The stone seat which runs round the walls of large churches, and sometimes round the piers; it very generally is placed in the porches.

Bevel. An instrument for taking angles. One side of a solid body is said to be beveled with respect to another, when the angle contained between those two sides is greater or less than a right angle.

Bezantee. A name given to an ornamental molding much used in the Norman period, resembling bezants, coins struck in Byzantium.

Billet. A species of ornamented molding much used in Norman, and sometimes in Early English work, like short pieces of stick cut off and arranged alternately.

Blocking, or **Blocking-course.** In masonry, a course of stones placed on the top of a cornice crowning the walls.

Bond. In bricklaying and masonry, that connection between bricks or stones formed by lapping them upon one another in carrying up the work, so as to form an inseparable mass of building, by preventing the vertical joints falling over each other. In brickwork there are several kinds of bond. In common brick walls in every sixth or seventh course the bricks are laid crossways of the wall, called Headers. In face work, the back of the face brick is clipped so as to get in a diagonal course of headers behind. In Old English bond, every alternate course is a header course. In Flemish bond, a header and stretcher alternate in each course.

Bond-stones. Stones running through the thickness of the wall at right angles to its face, in order to bind it together.

Bond-timbers. Timbers placed in a horizontal direction in the walls of a brick building in tiers, and to which the battens, laths, etc., are secured. In rubble work, walls are better plugged for this purpose.

Border. Useful ornamental pieces around the edge of anything.

Boss. An ornament, generally carved, forming the key-stone at the intersection of the ribs of a groined vault. Early Norman vaults have no bosses. The carving is generally foliage, and resembles that of the period in capitals, etc. Sometimes they have human heads, as at Notre Dame at Paris, and sometimes grotesque figures. In Later Gothic vaulting there are bosses at every intersection.

Boutell. The mediæval term for a round molding, or torus. When it follows a curve, as round a bench end, it is called a Roving Boutell.

Bow. Any projecting part of a building in the form of an arc of a circle. A bow, however, is sometimes polygonal.

Bow Window. A window placed in the bow of a building.

Brace. In carpentry, an inclined piece of timber, used in trussed partitions, or in framed roofs, in order to form a triangle, and thereby stiffen the framing. When a brace is used by way of support to a rafter, it is called a strut. Braces in partitions and span-roofs are, or always should be, disposed in pairs, and introduced in opposite directions.

Brace Mold. [{] Two ressaunts or ogees united together like a brace in printing, sometimes with a small bead between them.

Bracket. A projecting ornament carrying a cornice. Those which support vaulting shafts or cross-springers of a roof are more generally called Corbels.

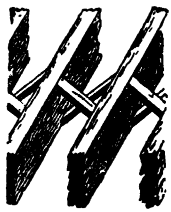
Break. Any projection from the general surface of a building.

Breaking Joint. The arrangement of stones or bricks so as not to allow two joints to come immediately over each other. See *Bond.*

Breast of a Window. The masonry forming the back of the recess and the parapet under the window-sill.

Bressummer. A lintel, beam, or iron tie, intended to carry an external wall and itself supported by piers or posts; used principally over shop windows. This term is now seldom used, the word *beam,* or *girder,* taking its place.

Bridging. A method of stiffening floor joist and partition studs, by cutting pieces in between. Cross-bridging of floor joist is illustrated in cut.



CROSS-BRIDGING

Bulwark. In ancient fortification, nearly the same as Bastion in modern.

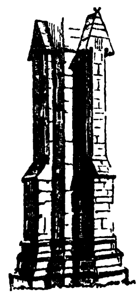
Burse, or **Bourse.** A public edifice for the assembly of merchant traders; an exchange.

Bust. In sculpture, that portion of the human figure which comprises the head, neck, and shoulders.

Buttery. A store-room for provisions.

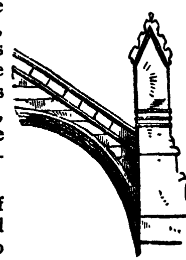
Butt-joint. Where the ends of two pieces of timber of molding butt together.

Buttress. Masonry projecting from a wall, and intended to strengthen the same against the thrust of a roof or vault. Buttresses are no doubt derived from the classic pilasters which serve to strengthen walls where there is a pressure of a girder or roof-timber. In very early work they have little projection, and, in fact, are " strippilasters." In Norman work they are wider, with very little projection, and generally stop under a cornice or corbel table. Early English buttresses project considerably, sometimes with deep sloping weatherings in several stages, and sometimes with gabled heads. Sometimes they are chamfered, and sometimes the angles have jamb shafts. At Wells and Salisbury, England, they are richly ornamented with canopies and statues. In the Decorated period they became richly paneled in stages, and often finish with niches and statues and elegantly carved and crocketed gablets, as at York, England. In the Perpendicular period the weatherings became waved, and they frequently terminate with niches and pinnacles.



BUTTRESS

Buttress, Flying. A detached buttress or pier of masonry at some distance from a wall, and connected therewith by an arch or portion of an arch, so as to discharge the thrust of a roof or vault on some strong point.



FLYING BUTTRESS

Buttress Shafts. Slender columns at the angle of buttresses, chiefly used in the Early English period.

Byzantine Architecture. A style developed in the Byzantine Empire. The capitals of the pillars are of endless variety and full of invention; some are founded on the Greek Corinthian, some resemble the Norman and the Lombard style, and are so varied that no two sides of the same capital are alike. They are comprised under the style Romanesque, which comprehends the round-arch style. Byzantine architecture reached its height in the Church of St. Sophia at Constantinople.

Cabinet. A highly ornamented kind of buffet or chest of drawers set apart for the preservation of things of value.

Cabling. The flutes of columns are said to be cabled when they are partly occupied by solid convex masses, or appear to be refilled with cylinders after they had been formed.

Caduceus. Mercury's rod, a wand entwined by two serpents and surmounted by two wings. The rod represents power; the serpents, wisdom; and the wings, diligence and activity.

CADUCEUS

Caisson. (1) A panel sunk below the surface in flat or vaulted ceilings. See *Cassoon.* (2) In bridge building, a chest or vessel in which the piers of a bridge are built, gradually sinking as the work advances till its bottom comes in contact with the bed of the river, and then the sides are disengaged, being so constructed as to allow of their being thus detached without injury to its floor or bottom. They are also used for foundations of buildings.

Caliber, or Caliper. The diameter of any round body; the width of the mouth of a piece of ordnance.

Camber. In carpentry, the convexity of a beam upon the surface, in order to prevent its becoming concave by its own weight, or by the burden it may have to sustain.

Campanile. A name given in Italy to the bell-tower of a town-hall or church. In that country this is almost always detached from the latter.

Canada, Architecture of. That of the British possessions to the north and northeast of the United States. The work of the aboriginal tribes included architectural features of great interest. Only the eastern section has developed architecturally.

Candelabrum. Stand or support on which the ancients placed their lamps. Candelabra were made in a variety of shapes and with much taste and elegance. The term is also used to denote a tall ornamental candlestick with several arms, or a bracket with arms for candles.

Canopy. The upper part or cover of a niche, or the projection or ornament over an altar, seat, or tomb. The word is supposed to be derived from conopæum, the gauze covering over a bed to keep off the gnats; a mosquito curtain. Early English canopies are generally simple, with trefoiled or cinque-foiled heads; but in the later styles they are very rich, and divided into compartments with pendants, knots, pinnacles, etc. The triangular arrangement over an Early English and Decorated doorway is often called a canopy. The triangular canopies in the North of Italy are peculiar. Those in England are generally part of the arrangement of the arch moldings of the door, and form, as it were, the hood-molds to them, as at York. The former are above and independent of the door moldings, and frequently support an arch with a tympanum, above which is a triangular canopy, as in the Duomo at Florence. Sometimes the canopy and arch project from the wall, and are carried on small jamb shafts, as at San Pietro Martiro at Verona. Canopies are often used

over windows, as at York Minster over the great west window, and lower ties in the towers. These are triangular, while the upper windows in the towers have ogee canopies.

Capital. The upper part of a column, pilaster, pier, etc. Capitals have been used in every style down to the present time. That mostly used by the Egyptians was bell-shaped, with or without ornaments. The Persians used the double-headed bell, forming a kind of bracket capital. The Assyrians apparently made use of the Ionic and Corinthian, which were developed by the Greeks, Romans, and Italians into their present well-known forms. The Doric was apparently an invention or adaptation by the Greeks, and was altered by the Romans and Italians. But in all these examples, both ancient and modern, the capitals of an order are all of the same form throughout the same building, so that if one be seen the form of all the others is known. The Romanesque architects altered all this, and in the carving of their capitals often introduced such figures and emblems as helped to tell the story of their building. Another form was introduced by them in the curtain capital, rude at first, but afterward highly decorated. It evidently took its origin from the cutting off of the lower angles of a square block, and then rounding them off. The process may be distinctly seen, in its several stages, in Mayence Cathedral. But this form of capital was more fully developed by the Normans, with whom it became a marked feature. In the early English capitals a peculiar flower of three or more lobes was used spreading from the necking upward in most graceful forms. In Decorated and Perpendicular styles this was abandoned in favor of more realistic forms of crumpled leaves, enclosing the bell like a wreath. In each style bold abacus moldings were always used, whether with or without foliage.

Caravansary. A huge, square building, or inn, in the East, for the reception of travelers and lodging of caravans

Carriage. The timber or iron joist which supports the steps of a wooden stair.

Carton, or **Cartoon.** A design made on strong paper, to be transferred on the fresh plaster wall to be afterward painted in fresco; also, a colored design for working in mosaic tapestry.

Cartouche. An ornament which like an escutcheon, a shield or an oval or oblong panel has the central part plain, and usually slightly convex, to receive an inscription, armorial bearings, or an ornamental or significant piece of painting or sculpture. Frequently used in French Renaissance and Modern Architecture.

CARYATID

Caryatides. Human female figures used as piers, columns or supports. *Caryatic* is applied to the human figure generally, when used in the manner of caryatides.

Cased. Covered with other materials, generally of a better quality.

Casement. A glass frame which is made to open by turning on hinges affixed to its vertical edges.

Cassoon, or **Caisson.** A deep panel or coffer in a soffit or ceiling. This term is sometimes written in the French form, *caisson;* sometimes derived directly from the Italian *cassone,* the augmentative of cassa, a chest or coffer.

Cast. A term used in sculpture for the impression of any figure taken in plaster of Paris, wax, or other substances.

Catacombs. Subterranean places for burying the dead. Those of Egypt, and near Rome, are believed to be the most important.

Catafalco. An ornamental scaffold used in funeral solemnities.

Cathedral. The principal church, where the bishop has his seat as diocesan.

Cauliculus. The inner scroll of the Corinthian capital. It is not uncommon, however, to apply this term to the larger scrolls or volutes also.

Causeway. A raised or paved way.

Cavetto. A concave ornamental molding, opposed in effect to the ovolo—the quadrant of a circle.

Ceiling. That covering of a room which hides the joists of the floor above, or the rafters of the roof. Most European churches either have open roofs, or are groined in stone. At Peterborough and St. Albans, England, there are very old flat ceilings of boards curiously painted. In later times the boarded ceilings, and, in fact, some of those of plaster, have molded ribs, locked with bosses at the intersection, and are sometimes elaborately carved. In many English churches there are ceilings formed of oak ribs, filled in at the spandrels with narrow, thin pieces of board, in exact imitation of stone groining. In the Elizabethan and subsequent periods the ceilings are enriched with most elaborate ornaments in stucco. Matched and beaded boards, planed and smoothed, used for wainscoting. In the New England States it is called sheathing.

Cenotaph. An honorary tomb or monument, distinguished from monuments in being empty, the individual it is to memorialize having received interment elsewhere.

Centaur. A poetical imaginary being of heathen mythology, half-man and half-horse.

Central America, Architecture of. That of the five states: Guatemala, Honduras, Nicaragua, San Salvador, and Costa Rica, and the colony of British Honduras. This region is rich in ruined structures that belong to the pre-Columbian class of American Architecture. The modern houses are usually small huts made of cane and palm leaves, or of sticks plastered with adobe mud, and whitewashed. In the towns adobe bricks are largely used, sometimes with a cut-stone foundation, as adobe disintegrates most rapidly near the ground. Aside from churches, which are numerous, there are few structures of importance.

Centring. In building, the frames on which an arch is turned.

Châlet. A wooden dwelling house of the type common in Switzerland The châlets are of two different types as for the structure: (1) The type derived from the log house, of heavy beams placed one upon the other and crossed at the angles; Oberland, Uri, Schwitz, etc.; (2) the framework building, a structure of posts and beams, with the wall merely filled in with thick boards, or even bricks, etc.; Zurich, Saint Gallen, Appenzell. A few châlets combine the two types.

Chamfer, Champfer, or **Chaumfer.** When the edge or arris of any work is cut off at an angle of 45° in a small degree, it is said to be chamfered; if to a large scale, it is said to be a canted corner. The chamfer is much used in mediæval work, and is sometimes plain, sometimes hollowed out, and sometimes molded.

Chamfer Stop. Chamfers sometimes simply run into the arris by a plane face; more commonly they are first stopped by some ornament, as by a bead·

they are sometimes terminated by trefoils, or cinquefoils, double or single, and in general form very pleasing features in mediæval architecture.

Chancel. A place separated from the rest of a church by a screen. The word is now generally used to signify the portion of a liturgical church containing the altar.

Chantry. A small chapel, generally built out from a church. They generally contain a founder's tomb, and are often endowed places where masses might be said for his soul. The officiator, or mass priest, being often unconnected with the parochial clergy. The chantry has generally an entrance from the outside.

Chapel. A small, detached building used as a substitute for a church in a large parish; an apartment in any large building, a palace, a nobleman's house, a hospital or prison, used for public worship; or an attached building running out of and forming part of a large church, generally dedicated to different saints, each having its own altar, piscina, etc., and screened off from the body of the building.

Chapter House. The chamber in which the chapter or heads of the monastic bodies assembled to transact business. They are of various forms; some are oblong apartments, some octagonal, and some circular.

Chaptrel. In Gothic architecture, the capital of a pier or column which receives an arch.

CHAPTREL

Charnel House. A place for depositing the bones which might be thrown up in digging graves. Sometimes it was a portion of the crypt; sometimes it was a separate building in the church-yard; sometimes chantry chapels were attached to these buildings. M. Viollet-le-Duc has given two very curious examples of *ossuaires*—one from Fleurance, the other from Faouet.

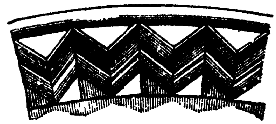
Charrette. (Fr.) Final period of work on design problem, a period of stress because of a fixed date of delivery.

China, Architecture of. Most ancient of nations, center of Asiatic civilization at different epochs, original source of Japanese culture, architecturally China yet remains, for European scholars, an unworked field. By three thousand years of civil wars, dynastic fighting, and Tartar and Mongol invasions all trace of palace or temple have been swept away. It is from the Japan architecture of fifty years since, that we must infer what we can of China's. In the Horiuji temples near Nara (Japan) are sixth-century structures built by Korean Architects; at this period Korea's art was that of China. Like the modern palaces, the ancient ones undoubtedly consisted of many small buildings crowded together, and very probably masonry entered largely into their construction, for we know that a thousand years before the Christian era brick was the common building material. The Hia dynasty was founded 2205 B.C. The fatal barbarism of Mongol and Manchu influences are everywhere visible in what passes for modern architecture, all that remains of architectural excellence being the dignity of great masses, and the contrast, often very agreeable, between light, generally wood-built superstructures, with the walls of the basements, as in the "Winter Palace" at Peiping, and its great gateway structures, and in some of the pagoda towers. The architecture of that imperial city and of the seaport towns is nearly all of a very recent period, and it is safe to conclude, in general, that the Chinese architecture of the last three hundred years is immeasurably inferior to that which must have gone before. That at one time Chinese architecture was a thing of the utmost beauty one cannot doubt. We know that the lofty civilization created by the

wise emperors of the Sung dynasty could have expressed itself only in noble art. The larger and more richly decorated of the now existing dwellings are interesting, because of the completely different ordering of the architectural members from that which is familiar to Europeans.

Cherub—Gothic. A representation of an infant's head joined to two wings, used in the churches on key-stones of arches and corbels.

Chevron—Gothic. An ornament turning this and that way, like a zigzag, or letter Z.



CHEVRON

Chiaroscuro. The effects of light and shade in a picture.

Choir. That part of a church or monastery where the breviary service, or "horæ," is chanted.

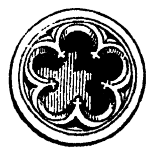
Christian Architecture. (1) Architecture of any style assumed to be especially under the influence of Christian religious belief. In this sense the English Gothic styles were called Christian by the Gothic revivalists of 1850 and thereafter. The styles which came of direct imitation of Greco-Roman architecture were considered pagan in contradistinction to that of the Middle Ages. (2) The architecture of the European world since the general triumph of Christianity. In this sense the earliest Christian Architecture is that of the basilicas and baptisteries of the reign of Constantine; and all buildings erected since that time in lands occupied or settled by Europeans are Christian, except where obviously the work of persons of other religions.

Church. A building for the performance of public worship. The first churches were built on the plan of the ancient basilicæ, and afterward on the plan of a cross: a church is said to be in Greek cross when the length of the transverse is equal to that of the nave; in Latin cross, when the nave is longer than the transverse part; in rotundo, when it is a perfect circle; simple, when it has only a nave and choir; with aisles, when it has a row of porticos in form of vaulted galleries, with chapels in its circumference.

Ciborium. A tabernacle or vaulted canopy supported on shafts standing over the high altar.

Cincture. A ring, list, or fillet at the top and bottom of a column, serving to divide the shaft of the column from its capital and base.

Cinquefoil. A sinking or perforation, like a flower, of five points or leaves, as a quatrefoil is of four. The points are sometimes in a circle. and sometimes form the cusping of a head.



CINQUEFOIL

Civic Crown. A garland of oak-leaves and acorns, given as honorary distinction among the Romans to such as had preserved the life of a fellow-citizen.

Clere-story, Clear-story. When the middle of the nave of a church rises above the aisles and is pierced with windows, the upper story is thus called. Sometimes these windows are very small, being mere quatrefoils, or spherical triangles. In large buildings, however, they are important objects both for beauty and utility. The window of the clere-stories of Norman work, even in large churches, are of less importance than in the later styles. In Early English they became larger; and in the Decorated they are more important still, being lengthened as the triforium diminishes. In Perpendicular work the latter often disappears altogether, and in many later churches the clere-

stories are close ranges of windows. The word *clere-story* is also used to denote a similar method of lighting other buildings besides churches, especially factories, depots, sheds, etc.

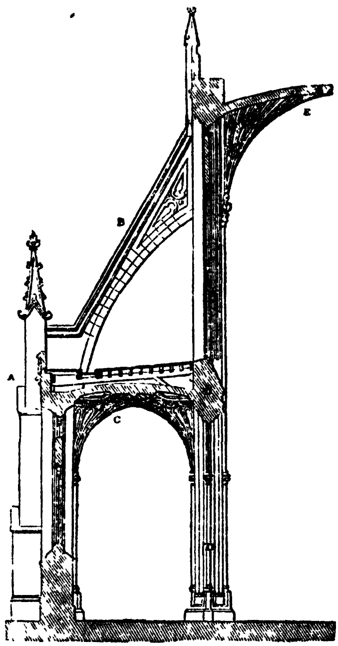
Cliff-Dwelling. An Amerindian house built in a cliff, either in a cave-like opening, a gallery, or on a ledge. Especially applied to structures in the cliffs of the Southwestern United States and Northern Mexico, built by Indians similar to the present Pueblos.

Cloister. An enclosed square, like the atrium of a Roman house, with a walk or ambulatory around, sheltered by a roof, generally groined, and by tracery windows, which were more or less glazed.

Close. The precinct of a cathedral or abbey. Sometimes the walls are traceable, but now generally the boundary is only known by tradition.

Close String, or **Box String.** A method of finishing the outer edge of stairs, by building up a sort of curb string on which the balusters set, and the treads and risers stop against it.

Clustered. In architecture, the coalition of several members which penetrate each other.



Bath Abbey

FLYING BUTTRESS AND CLERE-STORY

A, buttress with pinnacle; *B*, flying buttress supporting clere-story; *C*, vaulted roof of aisle; *D D*, pier dividing nave from aisle; *E*, vaulted roof of nave

Clustered Column. Several slender pillars attached to each other so as to form one. The term is used in Roman architecture to denote two or four columns which appear to intersect each other at the angle of a building to answer at each return.

Coat. A thickness or covering of paint, plaster, or other work, done at one time. The first coat of plastering is called the scratch coat, the second coat (when there are three coats) is called the brown coat, and the last coat is variously known as the slipped coat, skimcoat, or white coat. It varies in composition in different localities.

Coffer. A deep panel in a ceiling.

Coffer Dam. A frame used in the building of a bridge in deep water, similar to a caisson.

Collar Beam. A beam above the lower ends of the rafters, and spiked to them.

CLUSTERED COLUMN

Colonial Architecture. The architecture of a colony or colo-

nies; especially in American use as late as the beginning of the nineteenth century. (See *Georgian Architecture.*)

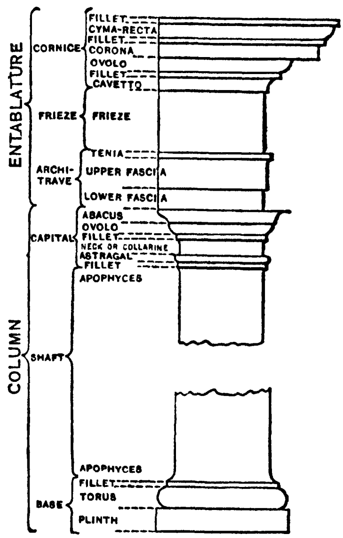
Colonnade. A row of columns. The colonnade is termed, according to the number of columns which support the entablature: Tetrastyle, when there are four; hexastyle, when six; octostyle, when eight, etc. When in front of a building they are termed porticos; when surrounding a building, peristyle; and when double or more, polystyle.

Colosseum, or Coliseum. The immense amphitheater built at Rome by Flavius Vespasian, A.D. 72, after his return from his victories over the Jews. It would contain ninety thousand persons sitting, and twenty thousand more standing. The name is now employed to denote an unusually large audience building, generally of a temporary nature.

Colossus. The name of a brazen statue which was erected at the entrance of the harbor at Rhodes, one hundred and five feet in height. Vessels could sail between its legs.

Column. A round pillar. The parts are the base, on which it rests; its body, called the shaft; and the head, called the capital. The capital finishes with a horizontal table, called the abacus, and the base commonly stands on another, called the plinth. Columns may be either insulated or attached. They are said to be attached or engaged when they form part of a wall, projecting one-half or more, but not the whole, of their substance.

Common. A line, angle, surface, etc., which belongs equally to several objects. Common centring is a centring without trusses, having a tie beam at bottom. Common joists are the beams in naked flooring to which the joists are fixed. Common rafters in a roof are those to which the laths are attached.



SECTION OF COLUMN AND ENTABLATURE

Composite Arch. Is the pointed or lancet arch.

Composite Order. The most elaborate of the orders of classical architecture.

Compound Arch. A usual form of mediæval arch, which may be resolved into a number of concentric archways, successively placed within and behind each other.

Concour. (Fr.) Competition.

Conduit. A long narrow passage between two walls or underground for secret communication between different apartments; also, a canal or pipe for the conveyance of water.

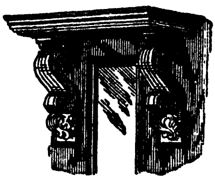
Confessional. The seat where a priest or confessor sits to hear confessions.

Conge. Another name for the echinus or quarter round.

Conservatory. A building for the protection and rearing of tender plants, often attached to a house as an apartment. Also, a public place of instruction, designed to preserve and perfect the knowledge of some branch of learning or the fine arts; as a *conservatory* of music.

Consistory. The judicial hall of the College of Cardinals at Rome.

Consol, or Console. A bracket or truss, generally with scrolls or volutes at the two ends, of unequal size and contrasted, but connected by a flowing line from the back of the upper one to the inner convolving face of the lower.



CONSOLES

Coping. The capping or covering of a wall. This is of stone, weathered to throw off the wet. In Norman times, as far as can be judged from the little there is left, it was generally plain and flat, and projected over the wall with a floating to form a drip. Afterward it assumed a torus or bowtell at the top, and became deeper, and in the Decorated period there were generally several off-sets. The copings in the Perpendicular period assumed something of the wavy section of the buttress caps, and mitred round the sides of the embrasure, as well as the top and bottom.

Corbel. The name, in mediæval architecture, for a piece of stone jutting out of a wall to carry any superincumbent weight. A piece of timber projecting in the same way was called a tassel or a bragger. Thus, the carved ornaments from which the vaulting shafts spring at Lincoln are corbels. Norman corbels are generally plain. In the Early English period they are sometimes elaborately carved. They sometimes end with a point, apparently growing into the wall, or forming a knot, and often are supported by angles and other figures. In the later periods the foliage or ornaments resemble those in the capitals. In modern architecture, a short piece of stone or wood projecting from a wall to form a support, generally ornamented.

Corbel Out. To build out one or more courses of brick or stone from the face of a wall, to form a support for timbers.

Corbel Table. A projecting cornice or parapet, supported by a range of corbels a short distance apart, which carry a molding, above which is a plain piece of projecting wall forming a parapet, and covered by a coping. Sometimes small arches are thrown across from corbel to corbel, to carry the projection.

Cornice. The projection at the top of a wall finished by a blocking-course, common in classic architecture. In Norman times, the wall finished with a corbel table, which carried a portion of plain projecting work, which was finished by a coping, and the whole formed a parapet. In Early English times the parapet was much the same, but the work was executed in a much better way, especially the small arches connecting the corbels. In the Decorated period the corbel table was nearly abandoned, and a large hollow, with one or two subordinate moldings, substituted; this is sometimes filled with the ball-flowers, and sometimes with running foliages. In the Perpendicular style the parapet frequently did not project beyond the wall-line below; the molding then became a string (though often improperly called a cornice), and was ornamented by a quatrefoil, or small rosettes, set at equal intervals immediately under the battlements. In many French examples the molded string is very bold. and enriched with foliage ornaments.

Corona. The brow of the cornice which projects over the bed moldings to throw off the water.

Corridor. A long gallery or passage in a mansion connecting various apartments and running round a quadrangle. Any long passageway in a building.

Countersink. To make a cavity for the reception of a plate of iron, or the head of a screw or bolt, so that it shall not project beyond the face of the work.

Coupled Columns. Columns arranged in pairs.

Course. A continued layer of bricks or stones in buildings; the term is also applicable to slates, shingles, etc.

Court. An open area behind a house, or in the center of a building and the wings. Courts admit of the most elegant ornamentations, such as arcades, etc.

Cove, Coving. The molding called the cavetto, or the scotia inverted, on a large scale, and not as a mere molding in the composition of a cornice, is called a cove or a coving.

Cove-bracketing. The wooden skeleton mold or framing of a cove, applied chiefly to the bracketing of a cove ceiling.

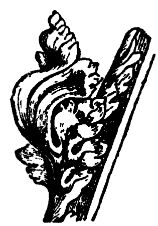
Cove Ceiling. A ceiling springing from the walls with a curve.

Coved and Flat Ceiling. A ceiling in which the section is the quadrant of a circle, rising from the walls and intersecting in a flat surface.

Cradling. Timber work for sustaining the lath and plaster of vaulted ceilings.

Cresting. An ornamental finish in the wall or ridge of a building, which is common on the Continent of Europe. An example occurs at Exeter Cathedral, the ridge of which is ornamented with a range of small fleurs-de-lis in lead.

Crocket. An ornament running up the sides of gablets, hood-molds, pinnacles, spires; generally, a winding stem like a creeping plant, with flowers or leaves projecting at intervals, and terminating in a finial.



CROCKET

Cross. This religious symbol is almost always placed on the ends of gables, the summit of spires, and other conspicuous places of old churches. In early times it was generally very plain, often a simple cross in a circle. Sometimes they take the form of a light cross, crosslet, or a cross in a square. In the Decorated and later styles they became richly floriated, and assumed an endless variety of forms. Of memorial crosses the finest examples are the Eleanor crosses, erected by Edward I. Of these a few yet remain, one of which has recently been reërected at Charing Cross. Preaching crosses were often set up by the wayside as stations for preaching; the most noted is that in front of St. Paul's, England. The finest remaining sepulchral crosses are the old elaborately carved examples found in Ireland.

Cross-aisle. An old name for a transept.

Cross-springer. The transverse ribs of a vault.

Cross-vaulting. A common name given to groins and cylindrical vaults.

Crown. In architecture the uppermost member of the cornice; called also Corona and Larmier.

Crypt. A vaulted apartment of greater or less size, usually under the choir.

Cupola. A small room, either circular or polygonal, standing on the top of a dome. By some it is called a Lantern.

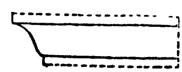
Curb Roof, or Mansard Roof. A roof formed of four contiguous planes, each two having an external inclination.

Curtail Step. The first step in a stair, which is generally finished in the form of a scroll.

Cusp. The point where the foliations of tracery intersect. The earliest example in England of a plain cusp is probably that at Pythagoras School, at Cambridge, of an ornamental cusp, at Ely Cathedral, where a small roll, with a rosette at the end, is formed at the termination of a cusp. In the later styles the terminations of the cusps were more richly decorated; they also sometimes terminate not only in leaves or foliages, but in rosettes, heads, and other fanciful ornaments.

Cyclostyle. A structure composed of a circular range of columns without a core is cyclostylar; with a core, the range would be a peristyle. This is the species of edifice called by Vitruvius monopteral.

Cyma. The name of a molding of very frequent use. It is a simple, waved line, concave at one end and convex at the other, like an italic *f*. When the concave part is uppermost it is called a cyma recta, but if the convexity appear above, and the concavity below, it is then a cyma reversa.



CYMA RECTA

Cymatium. When the crowning molding of an entablature is of the cyma form, it is termed the Cymatium.

CYMA REVERSA

Cyrtostyle. A circular projecting portico. Such are those of the transept entrances of St. Paul's Cathedral, London.

Dado, or Die. The vertical face of an insulated pedestal between the base and cornice, or surbase. It is extended also to the similar part of all stereobates which are arranged like pedestals in Roman and Italian architecture.

Dais. A part of the floor at the end of a mediæval hall, raised a step above the rest of the floor. On this the lord of the mansion dined with his friends at the great table, apart from the retainers and servants. In mediæval halls there was generally a deep recessed bay window at one or at each end of the dais, supposed to be for retirement, or greater privacy than the open hall could afford. In France the word is understood as a canopy or hanging over a seat; probably the name was given from the fact that the seats of great men were then surmounted by such an ornament.

Darby. A flat tool used by plasterers in working, especially on ceilings. It is generally about seven inches wide and forty-two inches long, with two handles on the back.

Decastyle. A portico of ten columns in front.

Decorated Style. The second stage of the Pointed or Gothic style of architecture, considered the most complete and perfect development of Gothic architecture, the best examples of which are found in England.

Demi-metope. The half of a metope, which is found at the retiring or projecting angles of a Doric frieze.

Denmark, Architecture of. The peninsula of Jutland as far south as Ribe, the islands of Zealand, Funen, Laaland, and Borneholm, with some smaller islands, are the territories properly included in Denmark. In considering the architecture of the region it is to be noted that its influence on the rest of Europe has been slight, and, however attractive the buildings are to the traveler, they have never been studied with any thoroughness. The earliest buildings of consequence are the round churches, of which four are on the island of Borneholm, one on the island of Funen, two on the island of Zealand, and one only on the mainland. They are generally alike in having a choir of great length, and the entrance porch at the opposite side sometimes carried up into a tower. Other churches in Denmark are generally Romanesque, simple in character such as corresponds to the plainer churches of the second half of the twelfth century in Germany. A curious cruciform church without aisles has five towers, a square one at the crossing and an octagonal one at the end of each arm of the cross; as no group of towers known has greater possibilities, it would have been interesting had the Gothic builders pushed the scheme to a final result. The Danish builders took a marked interest in the German Neoclassic Architecture of the sixteenth or seventeenth centuries, although there are many signs of independent thought. A most interesting state house, and two royal castles with lofty dormers are mainly of the sixteenth century. Later buildings are of the fantastic eighteenth century. The principal royal palace is of simple and tasteful design.

Dentil. The cogged or toothed member, common in the bed-mold of a Corinthian entablature, is said to be dentiled, and each cog or tooth is called a dentil.

Depressed Arches, or Drop Arches. Those of less pitch than the equilateral.

Design. The plans, elevations, sections, and whatever other drawings may be necessary for an edifice, exhibit the design, the term plan having a restricted application to a technical portion of the design.

Detail. As used by architects, detail means the smaller parts into which a composition may be divided. It is applied generally to moldings and other enrichments, and again to their minutiæ.

Diameter. The line in a circle passing through its center, or thickest part, which gives the measure proportioning the intercolumniation in some of the orders.

Diameters. The diameters of the lower and upper ends of the shaft of a column are called its inferior and superior diameters, respectively; the former is the greatest, the latter the least diameter of the shaft

Diaper. A method of decorating a wall, panel, stained glass, or any plain surface, by covering it with a continuous design of flowers, rosettes, etc., either in squares or lozenges, or some geometrical form resembling the pattern of a diapered table-cloth, from which, in fact, the name is supposed by some to have been derived.

Diastyle. A spacious intercolumniation, to which three diameters are assigned.

Dipteros. A double-winged temple. The Greeks are said to have constructed temples with two ranges of columns all around, which were called dipteroi. A portico projecting two columns and their interspaces is of dipteral or pseudo-dipteral arrangement.

Discharging Arch. An arch over the opening of a door or window, to discharge or relieve the superincumbent weight from pressing on the lintel.

Distemper. Term applied to painting with colors mixed with size or other glutinous substance. All the cartoons of the ancients, previous to the year 1410, are said to be done in distemper.

Distyle. A portico of two columns. This is not generally applied to the mere porch with two columns, but to describe a portico with two columns *in antis*.

Ditriglyph. As intercolumniation in the Doric order, of two triglyphs.

Dodecastyle. A portico of twelve columns in front. The lower one of the west front of St Paul's Cathedral, London, is of twelve columns, but they are coupled, making the arrangement pseudo-dodecastyle. The Chamber of Deputies in Paris has a true dodecastyle.

Dog-tooth. A favorite enrichment used from the latter part of the Norman period to the early part of the Decorated. It is in the form of a four-leaved flower, the center of which projects, and probably was named from its resemblance to the dog-toothed violet.

Dome. A cupola or inverted cup on a building. The application of this term to its generally received purpose is from the Italian custom of calling an archiepiscopal church, by way of eminence, Il Duomo, the temple; for to one of that rank, the Cathedral of Florence, the cupola was first applied in modern practice. The Italians themselves never call a cupola a dome; it is on this side of the Alps the application has arisen, from the circumstance, it would appear, that the Italians use the term with reference to those structures whose most distinguishing feature is the cupola, tholus, or (as we now call it) dome.

Domestic Architecture. That branch which relates to private buildings.

Donjon. The principal tower of a castle, generally containing the prison.

Door Frame. The surrounding case into and out of which the door shuts and opens. It consists of two upright pieces, called jambs, and a head, generally fixed together by mortices and tenons, and wrought, rebated, and beaded.

Doric Order. The oldest of the three orders of Grecian architecture.

Dormer Window. A window belonging to a room in a roof, which consequently projects from it with a valley gutter on each side. They are said not to be earlier than the fourteenth century. In Germany there are often several rows of dormers, one above the other. In Italian Gothic they are very rare; in fact, the former have an unusually steep roof, while in the latter country, where the Italian tile is used, the roofs are rather flat.

Dormitory. A room, suite of rooms, or building used to sleep in. The name was first applied to the place where the monks slept at night. It was sometimes one long room like a barrack, and sometimes divided into a succession of small chambers or cells. The dormitory was generally on the first floor, and connected with the church, so that it was not necessary to go out of doors to attend the nocturnal services. In the large houses of the Perpendicular period, and also in some of the Elizabethan, the entire upper story in the roof formed one large apartment, said to have been a place for exercise in wet weather, and also for a dormitory for the retainers of the household, or those of visitors.

Double Vault. Formed by a duplicate wall; wine cellars are sometimes so formed.

Dovetailing. In carpentry and joinery, the method of fastening boards or other timbers together, by letting one piece into another in the form of the expanded tail of a dove.

Dowel. A pin let into two pieces of wood or stone, where they are joined together. A piece of wood driven into a wall so that other pieces may be nailed to it. This is also called plugging.

Draw-bridge. A bridge made to draw up or let down, much used in fortified places. In navigable rivers, the arch over the deepest channel is made to draw or revolve, in order to let the masts of ships pass through.

Drawing-room. A room appropriated for the reception of company; a room to which company withdraws from the dining-room

Dresser. A cupboard or set of shelves to receive dishes and cooking utensils.

Dressing. Is the operation of squaring and smoothing stones for building; also applied to smoothing lumber.

Dressing-room. An apartment appropriated for dressing the person.

Drip. A name given to the member of a cornice which has a projection beyond the other parts for throwing off water by small portions, drop by drop. It is also called Larmier.

Drip-stone. The label molding which serves on a canopy for an opening, and to throw off the rain. It is also called Weather Molding.

Drop-scene. A curtain suspended by pulleys, which descends or drops in front of the stage in a theater.

Drum. The upright part of a cupola over a dome; also, the solid part or vase of the Corinthian and Composite capitals.

Dry-rot. A rapid decay of timber, by which its substance is converted into a dry powder, which issues from minute cavities resembling the borings of worms.

Dungeon. The prison in a castle keep, so called because the Norman name for the latter is donjon, and the dungeons, or prisons, are generally in its lowest story.

Dwarf Wall. The walls enclosing courts above which are railings of iron; low walls, in general, receive this name.

Eaves. In slating and shingling, the margin or lower part of the slating hanging over the wall, to throw the water off from the masonry or brickwork.

Echinus. A molding of eccentric curve, generally cut (when it is carved) into the forms of eggs and anchors alternating, whence the molding is called by the name of the more conspicuous. It is the same as Ovolo.

ECHINUS

Edifice. Is synonymous with the terms building, fabric, erection, but is more strictly applicable to architecture distinguished for size, dignity, and grandeur.

Efflorescence. In architecture, the formation of a whitish loose powder, or crust, on the surface of stone or brick walls.

Egyptian Architecture. The earliest civilization and cultivation of the arts was in Upper Egypt. The most remarkable and most ancient monuments of the Egyptians, with the exception of the pyramids, are nearly all included in Upper Egypt. The buildings of Egypt are characterized by solidity and mas-

siveness of construction, originality of conception, and boldness of form. The walls, the pillars, and the most sacred places of their religious buildings were ornamented with hieroglyphics and symbolical figures, while the ceilings of the porticos exhibited zodiacs and celestial planispheres. The temples of Egypt were generally without roofs, and, consequently, the interior colonnades had no pediments, supporting merely an entablature, composed of only architrave, frieze, and cornice, formed of immense blocks united without cement and ornamented with hieroglyphics.

Element. The outline of the design of a Decorated window, on which the centers for the tracery are formed. These centers will all be found to fall on points which, in some way or other, will be equimultiples of parts of the openings. To draw tracery well, or understand even the principles of its composition, much attention should be given to the study of the element.

Elevation. The front façade, as the French term it, of a structure; a geometrical drawing of the external upright parts of a building.

Elizabethan Architecture. The architecture of the reign and time of Queen Elizabeth in England. That which grew out of the Tudor style mainly by means of the great country houses built by noblemen and landholders in England.

Embattlement. An indented parapet; battlement.

Emblazon. To adorn with figures of heraldry, or ensigns armorial.

Embossing. Sculpture in rilievo, the figures standing partly out from the plane.

Embrasure. The opening in a battlement between the two raised solid portions or merlons, sometimes called a crenelle.

Encaustic. Pertaining to the art of burning in colors, applied to painting on glass, porcelain, or tiles, where colors are fixed by heat; hence, encaustic tiles, bricks, etc.

Engaged Columns. Are those attached to, or built into walls or piers, a portion being concealed.

England, Architecture of. The history of architecture in England begins with the history of her people; the styles of architecture were modified by the changes in the various political systems: Roman, Saxon and Norman were the influence in early times. From the French came the first inspiration for Gothic work, which went through its various phases into the Tudor. At that time the architectural interest centered on the domestic instead of the outstanding cathedrals and monasteries, and the Elizabethan, Queen Anne, and English classic are developed. The Oxford movement caused a study of all periods in the history of architecture, and resulted in the multiplicity of styles. Among them all there is, however, much that has a sterling ring. There is good sound Gothic, full of vigor and life; there is Gothic touched with the sixteenth-century spirit and Italian detail. There is classic, as of Wren, in its simple robustness, there is Renaissance of Flanders and the Lowlands; occasionally some French Renaissance There are Tudor, Elizabethan, and Jacobean, all these and more in Victoria's days.

Enrichment. The addition of ornament, carving, etc., to plain work; decoration; embellishment.

Ensemble. Means the whole work or composition considered together, and not in parts.

Entablature. The assemblage of parts supported by the column. It consists of three parts: the architrave, frieze, and cornice.

Entail. In Gothic architecture, delicate carving.

Entasis. The swelling of a column, etc. In mediæval architecture, some spires, particularly those called " broach spires," have a slight swelling in the sides, but no more than to make them look straight; for, from a particular " deceptio visus," that which is quite straight, when viewed at a height, looks hollow.

Entry. A hall without stairs or vestibule.

Epistyle. This term may with propriety be applied to the whole entablature, with which it is synonymous; but it is restricted in use to the architrave, or lowest member of the entablature.

Escutcheon. (Her.) The field or ground on which a coat-of-arms is represented. (Arch) The shields used on tombs, in the spandrels of doors, or in string-courses; also, the ornamented plates from the center of which door rings, knockers, etc., are suspended, or which protect the wood of the keyhole from the wear of the key. In mediæval times these were often worked in a very beautiful manner.

Eskimo Architecture. The architecture of the tribes occupying the polar shores and regions of North America, and to a limited extent Siberia, who are called Eskimos or Esquimaux.

Esquisse. (Fr.) Sketch from which project is developed with least possible deviation.

Esquisse-Esquisse. (Fr.) A quickly presented sketch problem.

Etching. A mode of engraving on glass or metal (generally copper) by means of lines, eaten in or corroded by means of some strong acid.

Etruscan Architecture. The remains of Etruscan architecture are so few that they might be passed over, were it not for the very important part they play in the foundation of Roman architecture. There are two classes: (1) Structures erected in stone have in part lasted to the present day; as the roads, walls and arched entrance gates; (2) those built of ephemeral materials have long since passed away, of which only conjecture can be made from writings of historians, collections in museums, and evidence given in designs of their tombs.

Eustyle. A species of intercolumniation to which a proportion of two diameters and a quarter is assigned. This term, together with the others of similar import—pycnostyle, systyle, diastyle, and aræostyle—referring to the distance of columns from one another in composition, is from Vitruvius, who assigns to each the space it is to express. It will be seen, however, by reference to them individually, that the words themselves, though perhaps sufficiently applicable convey no idea of an exactly defined space, and, by reference to the columnar structures of the ancients, that no attention was paid by them to such limitations. It follows, then, that the proportions assigned to each are purely conventional, and may or may not be attended to without vitiating the power of applying the terms. Eustyle means the best or most beautiful arrangement; but, as the effect of a columnar composition depends on many things besides the diameter of the columns, the same proportioned intercolumniation would look well or ill according to those other circumstances, so that the limitation of Eustyle to two diameters and a quarter is absurd.

Exedra. In classical archæology, a place partly enclosed and roofed over, and provided with seats; also, a covered room or hall opening from a colonnade, and arranged as a lecture-room or court-room; an outhouse, or shed; a hall for meetings. In English usage, usually a semicircular, or nearly semi-

circular, raised seat, the back of which forms a low wall, and especially one of considerable size and of some pretensions. This sense is derived from the rounded apses of the Roman basilicas, which were fitted with a permanent seat, and served regularly, or on special occasions, for court-rooms.

Exercise en loge. (Fr.) Drawings prepared without assistance, criticism, or the use of documents.

Extrados. The exterior or convex curve forming the upper line of the arch stones; the term is opposed to the intrados, or concave side.

Eye of a Dome. The apperture at its summit.

Eye of a Volute. The circle in its center.

Façade, or Face. The whole exterior side of a building that can be seen at one view; strictly speaking, the principal front.

Face Mold. The pattern for marking the plank or board out of which ornamental hand-railings for stairs and other works are cut.

Fan Tracery. The very complicated mode of roofing used in the Perpendicular style, in which the vault is covered by ribs and veins of tracery.

Fascia. A flat, broad member in the entablature of columns or other parts of buildings, but of small projection. The architraves in some of the orders are composed of three bands, or fasciæ; the Tuscan and the Doric ought to have only one. Ornamental projections from the walls of brick buildings over any of the windows, except the uppermost, are called Fasciæ.

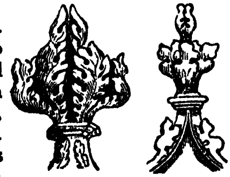
Fenestral. A frame, or "chassis," on which oiled paper or thin cloth was strained to keep out wind and rain when the windows were not glazed.

Festoon. An ornament of carved work, representing a wreath or garland of flowers or leaves, or both, interwoven with each other. It is thickest in the middle, and small at each extremity, where it is tied, a part often hanging down below the knot.

FESTOON

Fillet. A narrow vertical band or listel of frequent use in congeries of moldings, to separate and combine them, and also to give breadth and firmness to the upper edge of a crowning cyma or cavetto, as in an external cornice. The narrow slips of breadth between the flutes of Corinthian and Ionic columns are also called fillets. In mediæval work the fillet is a small, flat, projecting square, chiefly used to separate hollows and rounds, and often found in the outer parts of shafts and boutels. In this situation the center fillet has been termed a keel, and the two side ones, wings; but, apparently, this is not an ancient usage.

Finial. The flower, or bunch of flowers, with which a spire, pinnacle, gablet, canopy, etc., generally terminates. Where there are crockets, the finial generally bears as close a resemblance as possible to them in point of design. They are found in early work where there are no crockets. The simplest form more resembles a bud about to burst than an open flower. They soon became more elaborate, as at Lincoln, and still more, as at Westminster and the Hôtel Cluny at Paris. Many perpendicular finials are like four crockets bound together. Almost every known example of a finial has a sort of necking separating it from the parts below.



FINIALS

Fireplace. That part of a building which is arranged for the making of fires, as for warmth; especially, such a provision when made for open fires of coal or wood, as distinguished from furnaces, stoves, or the elaborate holocaust of the Romans. In this sense the fireplace is either the hearth in the middle of the room, as common in primitive times, the smoke escaping through openings in the roof, or a part of a chimney. The latter sense is the ordinary use of the term fireplace, and implies a recess in the wall or chimney-breast which connects directly with a flue for smoke. It is a recess or a space enclosed by two jambs or cheeks, and terminating above in the flue. The decoration of the fireplace has always been important, because that one part of the room is wholly different in its uses, and probably in its material as well, from the rest.

Fish-joint. A splice where the pieces are joined butt end to end, and are connected by pieces of wood or iron placed on each side and firmly bolted to the timbers, or pieces joined.

Flags. Flat stones, from 1 to 3 inches thick, for floors.

Flamboyant. A name applied to the Third Pointed style in France, which seems to have been developed from the Second, as the English Perpendicular was from the Decorated. The great characteristic is, that the element of the tracery flows upward in long wavy divisions like flames of fire. In most cases, also, every division has only one cusp on each side, however long the division may be. The moldings seem to be as much inferior to those of the preceding period as the Perpendicular moldings were to the Early English, a fact which seems to show that the decadence of Gothic architecture was not confined to one country.

Flange. A projecting edge, rib, or rim. Flanges are often cast on the top or bottom of iron columns, to fasten them to those above or below; the top and bottom of I-beams and channels are called the flange.

Flashings. Pieces of lead, tin, or copper, let into the joints of a wall so as to lap over gutters or other pieces; also, pieces worked in the slates or shingles around dormers, chimneys, and any rising part, to prevent leaking.

Flatting. Painting finished without leaving a gloss on the surface.

Flèche. A general term in French architecture for a spire, but more particularly used for the small, slender erection rising from the intersection of the nave and transepts in cathedrals and large churches, and carrying the sanctus bell.

Fleur-de-lis. The royal insignia of France, much used in decoration.

Flight. A run of steps or stairs from one landing to another.

Floating. The equal spreading of plaster or stucco on the surface of walls, by means of a board called a float; as a rule, only rough plastering is floated.

Floriated. Having florid ornaments, as in Gothic pillars.

Flue. The space or passage in a chimney through which the smoke ascends. Each passage is called a flue, while all together make the chimney.

Flush. The continued surface, in the same plane, of two contiguous masses.

Flute. A concave channel. Columns whose shafts are channeled are said to be fluted, and the flutes are collectively called Flutings.

Flying Buttress. An arched buttress used when extra strength was required for the upper part of the wall of the nave, etc., to resist the outward thrust of a vaulted ceiling. The flying buttress generally rests on the wall and buttress of the aisle.

Foils. The small arcs in the tracery of Gothic windows, panels, etc.

Foliage. An ornamental distribution of leaves on various parts of buildings.

Foliation. The use of small arcs or foils in forming tracery.

Font. The vessel used in the rite of baptism. The earliest extant is supposes to be that in which Constantine is said to have been baptized; this is a porphyry labrum from a Roman bath. Those in the baptisteries in Italy are all large, and were intended for immersion; as time went on, they seem to have become smaller. Fonts are sometimes mere plain hollow cylinders, generally a little smaller below than above; others are massive squares, supported on a thick stem, round which sometimes there are smaller shafts. In the Early English this form is still pursued, and the shafts are detached; sometimes, however, they are hexagonal and octagonal, and in this and the later styles assume the form of a vessel on a stem. Norman fonts frequently have curious carvings on them, approaching the grotesque; in later times the foliages, etc., partook absolutely of the character of those used in other architectural details of their respective periods. The font in European churches is usually placed close to a pillar near the entrance, generally that nearest but one to the tower in the south arcade; or, in large buildings, in the middle of the nave, opposite the entrance porch, and sometimes in a separate building. In Protestant churches in this country, the font is generally placed inside the communion rail, or on the steps of the chancel.

Footings. The spreading courses at the base or foundation of a wall. When a layer of different material from that of the wall (as a bed of concrete) is used, it is called the Footing.

Foundation. That part of a building or wall which is below the surface of the ground.

Foxtail Wedging. Is a peculiar mode of mortising, in which the end of the tenon is notched beyond the mortise, and is split and a wedge inserted, which, being forcibly driven in, enlarges the tenon and renders the joint firm and immovable.

Frame. The name given to the wood-work of windows, doors, etc.: and in carpentry, to the timber works supporting floors, roofs, etc.

Framing. The rough timber work of a house, including the flooring, roofing, partitioning, ceiling, and beams thereof.

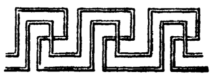
France, Architecture of. The architecture of the modern state of France; it should be divided into its various architectural sections. This region was all included in the Roman Gallia, and Roman remains are found in all parts. Many of the sections were independent states, or nearly so, and as architecture is developed according to the mode of living, each province should be taken separately to understand the architectural vicissitudes of France. The mere mentioning of a few of these divisions, like Parisian France, Flemish France, Normandy, Brittany, tells the diversity of the people. This paragraph, however, will treat France as a whole, and the simple statement will be made that it was not until the beginning of the Renaissance that the country became one in the modern sense. France is the richest country in Europe in buildings of value to the Western student (later than the time of the fall of the Roman Imperial dominion). In the eleventh century France takes the lead in Europe, with noblest and richest as well as most varied Romanesque. In the twelfth century the lead is still more decided, in spite of the magnificent German round-arched cathedrals, for the Gothic art beginning about 1150 is entirely French in the strictest sense, all the other European lands having

taken their primary and most of their subsequent impulses from the French royal domain. Practically the same may be said of the works of the later Gothic style and of the Renaissance in France, which developed the styles of Louis XV and XVI. Present-day architecture is deserting the conventional, and the final development is awaited with interest. On the whole, then, the architecture of France since the beginning of the Romanesque period is the most important for the modern student.

Freestone. Stone which can be used for molding, tracery, and other work required to be executed with the chisel. The oolitic and sandstone are those generally included by this term.

Fresco. The method of painting on a wall while the plastering is wet. The color penetrates through the material, which, therefore, will bear rubbing or cleaning to almost any extent. The transparency, the chiaroscuro, and lucidity, as well as force, which can be obtained by this method, cannot be conceived unless the frescos of Fra Angelico or Raphael are studied. The word, however, is often applied improperly to painting on the surface in distemper or body color, mixed with size or white of egg, which gives an opaque effect.

Fret. An ornament consisting of small fillets intersecting each other at right angles.



FRET

Frieze. That portion of an entablature between the cornice above and and architrave below. It derives its name from being the recipient of the sculptured enrichments either of foliage or figures which may be relevant to the object of the sculpture. The frieze is also called the Zoösphorus.

Frigidarium. An apartment in the Roman bath, supplied with cold water.

Furniture. Formerly a name given to the metal trimmings of doors, windows, and other similar parts of a house. In this country the word "hardware" is more generally used to denote the same thing. Household furnishings.

Furrings. Flat pieces of timber used to bring an irregular framing to an even surface.

Gable. When a roof is not hipped or returned on itself at the ends, its ends are stopped by carrying up the walls under them in the triangular form of the roof itself. This is called the gable, or, in the case of the ornamental and ornamented gable, the pediment. Of necessity, gables follow the angles of the slope of the roof, and differ in the various styles. In Norman work they are generally about half-pitch; in Early English, seldom less than equilateral, and often more. In Decorated work they become lower, and still more so in the Perpendicular style. In all important buildings they are finished with copings or parapets. In the Later Gothic styles gables are often surmounted with battlements, or enriched with crockets; they are also often paneled or perforated, sometimes very richly. The gables in ecclesiastical buildings are mostly terminated with a cross; in others, by a finial or pinnacle. In later times the parapets or copings were broken into a sort of steps, called corbic steps. In buildings of less pretension the tiles or other roof covering passed over the front of the wall, which then, of course, had no coping. In this case, the outer pair of rafters were concealed by molded or carved verge boards.

Gable Window. A term sometimes applied to the large window under a gable, but more properly to the windows in the gable itself.

Gabled Towers. Those which are finished with gables instead of parapets. Many of the German Romanesque towers are gabled.

Gablets. Triangular terminations to buttresses, much in use in the Early English and Decorated periods, after which the buttresses generally terminate in pinnacles. The Early English gablets are generally plain, and very sharp in pitch. In the Decorated period they are often enriched with paneling and crockets. They are sometimes finished with small crosses, but oftener with finials.

Gain. A beveled shoulder on the end of a mortised brace, for the purpose of giving additional resistance to the shoulder.

Gallery. Any long passage looking down into another part of a building, or into the court outside. In like manner, any stage erected to carry a rood or an organ, or to receive spectators, was latterly called a gallery, though originally a loft. In later times the name was given to any very long rooms, particularly those intended for purposes of state, or for the exhibition of pictures.

Gambrel Roof. A roof with two pitches, similar to a mansard or curb roof.

Gargoyle, or Gurgoyle. The carved termination to a spout which conveyed away the water from the gutters, supposed to be called so from the gurgling noise made by the water passing through it. Gargoyles are mostly grotesque figures.

GARGOYLE

Gate-house. A building forming the entrance to a town, the door of an abbey, or the enceinte of a castle or other important edifice. They generally had a large gateway protected by a gate, and also a portcullis, over which were battlemented parapets with holes (machicolations) for throwing down darts, melted lead, or hot sand on the besiegers. Gatehouses always had a lodge, with apartments for the porter, and guard-rooms for the soldiers; and, generally, rooms over for the officers, and often places for prisoners beneath. The name is now commonly applied to the gate-keeper's lodge on large estates.

Gauge. To mix plaster of Paris with common plaster to make it set quickly, called gauged mortar. A tool used by carpenters, to strike a line parallel to the edge of a board.

Georgian Architecture. The architecture of the reigns of the four Georges in England—1714 to 1830. The term is more usually employed for that of the earlier reigns. Architecture of the same epoch in America has been called generally "Colonial," or "Old Colonial," but the term Georgian is applied to this also, as an expletive more accurate or more descriptive.

Germany, Architecture of. That of the states constituting the present Republic. Since it is inhabited by people of various races, languages, manners, and religions, one might reasonably expect great contrasts in architecture; but as a rule, whatever is borrowed from without or originates within is welded into an unmistakable German form. The early inhabitants appear to have commenced their architectural operations by scooping out caves in the rocks or hillsides. Examples remain of rock-cut churches. Fragments of Roman buildings exist all over Germany. Typical German work shows the highest reach of constructional excellence of the pure Romanesque style. An Eastern influence is conspicuous in the Romanesque buildings which chiefly exhibits itself in churches planned and constructed in cubes, polygons, and circles, covered with domical vaults, semidomes, and lunette vaulting. Gothic cathedrals have had an important influence on German architecture.

The present-day architecture of Germany is working along original lines and is dealing more in masses and undecorated surfaces.

Girder. A large timber or iron beam, either single or built up, used to support joists or walls over an opening.

Glyph. A vertical channel in a frieze.

Gothic Style. The name of Gothic was given to the various Mediæval styles at a period in the sixteenth century when a great classic revival was going on, and everything not classic was considered barbarian, or Gothic. The term was thus originally intended as one of stigma, and, although it conveys a false idea of the character of the Mediæval styles, it has long been used to distinguish them from the Grecian and Roman. The true principle of Gothic architecture is the vertical division, relation and subordination of the different parts, distinct and yet at unity with each other, and while this principle was adhered to, Gothic architecture may be said to have retained its vitality.

Grange. A word derived from the French, signifying a large barn or granary. Granges were usually long buildings with high wooden roofs, sometimes divided by posts or columns into a sort of nave and aisles, with walls strongly buttressed. In England the term was applied not only to the barns, but to the whole of the buildings which formed the detached farms belonging to the monasteries; in most cases there was a chapel either included among these or standing apart as a separate edifice.

Greco-Roman. An architecture of the beam and column, the lintel being used pure and unmixed by the Greeks, but forced into union with the arch by the Romans.

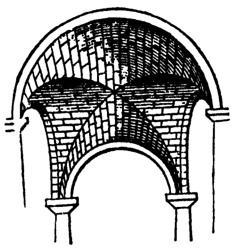
Greece, Architecture of. That of the Republic of Greece, South Balkan peninsula and neighboring islands. Architectural history may be divided into periods coinciding with the country's political history. The beginning of the prehistoric period is lost in the mists of antiquity. The ruins of massive fortification walls indicate a state of society resembling Feudal Europe in the Middle Ages. The surpassing loveliness of the scenery and the facility of intercourse with Oriental countries naturally served to stimulate the early artistic development of the people near the Argive Gulf, and Herodotus tells of the commercial attractions offered by this section of the Phoenician traders. The "classic" period (500 to 400 B.C.) is the culminating era. Artists had developed apace with rapid growth of wealth and refinement, and, as in the times of all good art, the architects, sculptors, and painters interlocked arms or were embodied in the same individuals. The octastyle Parthenon on the Athenian Acropolis represents the perfect Greek, temple. The beautiful Doric and Ionic temples are found in many places. Temples, stoas, gymnasia, stadia, theaters, gateways, propylæa, and acropolises reached perfection. The choragic monument of Lysicrates serves as a type for the Corinthian order. In Greece wood was originally used for column and entablature. Stone was gradually substituted, retaining and petrifying the traditional wooden forms. The stone columns were usually built of several drums, and were often given a thin coat of lime plaster and painted an orange yellow. When marble was used, its smooth surface rendered the plaster unnecessary. The members of the entablature, ceilings and carved ornaments were also painted, chiefly in reds, blues and yellows. The Byzantine period finds Greece still but a province of the vast Roman empire, and only small and unimportant examples remain. During the Turkish period (1453–1831) Greece lay prostrate. Then followed the modern period with Austrians and Germans designing most of her buildings.

Grillage. A framework of beams laid longitudinally and crossed by similar beams laid upon them, used to sustain walls to prevent irregular setting.

Grille. The iron-work forming the enclosure screen to a chapel, or the protecting railing to a tomb or shrine; more commonly found in France than in England. They are of wrought iron, ornamented by the swage and punch, and put together either by rivets or clips. In modern times grilles are used extensively for protecting the lower windows in city houses, also the glass opening in outside doors.

Groin. By some described as the line of intersection of two vaults where they cross each other, which others call the groin point; by others the curved section or spandrel of such vaulting is called a groin, and by others the whole system of vaulting is so named.

Groin Arch. The cross-rib in the later styles of groining, passing at right angles from wall to wall, and dividing the vault into bays or travees.



GROINED VAULTING

Groin Ceiling. A ceiling to a building composed of oak ribs, the spandrels of which are filled in with narrow, thin slips of wood. There are several in England; one at the Early English church at Warmington, and one at Winchester Cathedral, exactly resembling those of stone.

Groin Centring. In groining without ribs, the whole surface is supported by centring during the erection of the vaulting. In ribbed work the stone ribs only are supported by timber ribs during the progress of the work, any light stuff being used while filling in the spandrels.

Groin Point. The name given by workmen to the arris or line of intersection of one vault with another where there are no ribs.

Groin Rib. The rib which conceals the groin point or joints, where the spandrels intersect.

Groined Vaulting. The system of covering a building with stone vaults which cross and intersect each other, as opposed to the barrel vaulting, or series of arches placed side by side. The earliest groins are plain, without any ribs, except occasionally a sort of wide band from wall to wall, to strengthen the construction. In later Norman times ribs were added on the line of intersection of the spandrels, crossing each other, and having a boss as a key common to both; these ribs the French authors call *nerfs en ogive.* Their introduction, however, caused an entire change in the system of vaulting; instead of arches of uniform thickness and great weight, these ribs were first put up as the main construction, and spandrels of the lightest and thinnest possible material placed upon them, the haunches only being loaded sufficiently to counterbalance the pressure from the crown. Shortly after, half-ribs against the walls (formerets) were introduced to carry the spandrels without cutting into the walling, and to add to the appearance. The work was now not treated as continued vaulting, but as divided into bays, and it was formed by keeping up the ogive, or intersecting ribs and their bosses; a sort of construction having some affinity to the dome was formed, which added much to the strength of the groining. Of course, the top of the soffit or ridge of the vault was not horizontal, but rose from the level of the top of the formeret-rib to the boss and fell again; but this could not be perceived from below. As this system of construction got more into use, and as the vaults were required to be of greater span and of higher pitch, the spandrels became larger, and required more support. To

give this, another set of ribs was introduced, passing from the springers of the ogive ribs, and going to about half-way between these and the ogive, and meeting on the ridge of the vault; these intermediate ribs are called by the French *tiercerons*, and began to come into use in the transition from Early English to Decorated. About the same period a system of vaulting came into use called *hexpartite*, from the fact that every bay is divided into six compartments instead of four. It was invented to cover the naves of churches of unusual width. The filling of the spandrels in this style is very peculiar, and, where the different compartments meet at the ridge, some pieces of harder stone have been used, which give rather a pleasing effect. The arches against the wall, being of smaller span than the main arches, cause the center springers to be perpendicular and parallel for some height, and the spandrels themselves are very hollow. As styles progressed, and the desire for greater richness increased, another series of ribs, called *liernes*, was introduced; these passed crossways from the *ogives* to the *tiercerons*, and thence to the *doubleaux*, dividing the spandrels nearly horizontally. These various systems increased in the Perpendicular period, so that the walls were quite a net-work of ribs, and led at last to the Tudor, or, as it is called by many, fan-tracery vaulting. In this system the ribs are no part of the real construction, but are merely carved upon the voussoirs, which form the actual vaulting. Fan-tracery is so called because the ribs radiate from the springers, and spread out like the sticks of a fan. These later methods are not strictly groins, for the pendentives are not square on plan, but circular, and there is, therefore, no arris intersection or groin point.

Groins, Welsh, or Underpitch. When the main longitudinal vault of any groining is higher than the cross or transverse vaults which run from the windows, the system of vaulting is called underpitch groining, or, as termed by the workmen, Welsh groining. A very fine example is at St. George's Chapel, Windsor, England.

Groove. In joinery, a term used to signify a sunk channel whose section is rectangular. It is usually employed on the edge of a molding, stile, or rail, etc., into which a tongue corresponding to its section, and in the substance of the wood to which it is joined, is inserted.

Grotesque. A singular and fantastic style of ornament found in ancient buildings.

Grotto. An artificial cavern.

Ground Floor. The floor of a building on a level, or nearly so, with the ground.

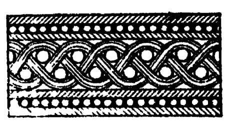
Ground Joist. Joist that is blocked up from the ground.

Grounds. Pieces of wood embedded in the plastering of walls to which skirting and other joiner's work is attached. They are also used to stop the plastering around door and window openings.

Grouped Columns. Three, four, or more columns put together on the same pedestal. When two are placed together, they are said to be coupled.

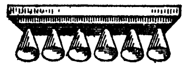
Grout. Mortar made so thin by the addition of water that it will run into all the joints and cavities of the mason-work, and fill it up solid.

Guilloche, or Guillochos. An interlaced ornament like net-work, used most frequently to enrich the torus.



GUILLOCHE

Guttæ. The small cylindrical drops used to enrich the mutules and regulæ of the Doric entablature are so called.



GUTTÆ

Gutter. The channel for carrying off rain-water. The mediæval gutters differed little from others, except that they are often hollows sunk in the top of stone cornices, in which case they are generally called channels in English, and *chcneaux* in French.

Gymnasium. A building classed in the first rank by the Greeks; it was in them they instructed the youth in all the arts of peace and war; a building for athletic exercises.

Hall. The principal apartment in the large dwellings of the Middle Ages. used for the purposes of reception, feasts, etc. In the Norman castle the hall was generally in the keep above the ground floor, where the retainers lived, the basement being devoted to stores and dungeons for confining prisoners. Later halls—indeed, some Norman halls (not in castles)—are generally on the ground floor, as at Westminster, approached by a porch either at the end, as in this last example, or at the side, as at Guildhall, London, having at one end a raised dais or estrade. The roofs are generally open and more or less ornamented. In the middle of these was an opening to let out the smoke, though in later times the halls have large chimney-places with funnels or chimney-shafts for this purpose. At this period there were usually two deeply recessed bay windows at each end of the dais, and doors leading into the withdrawing-rooms, or the ladies' apartments; they are also generally wainscoted with oak, in small panels, to the height of five or six feet, the panels often being enriched. Westminster Hall was originally divided into three parts, like a nave and side aisles, as are some on the Continent of Europe. A room or passageway at the entrance of a house, or suite of chambers. A place of public assembly as a town-hall, a music-hall.

Halving. The junction of two pieces of timber, by letting one into the other.

Hammer Beam. A beam in a Gothic roof, not extending to the opposite side; a beam at the foot of a rafter.

Hanging Buttress. A buttress not rising from the ground, but supported on a corbel, applied chiefly as a decoration and used only in the Decorated and Perpendicular styles.

Hanging Style. Of a door, is that to which the hinges are fixed.

Hangings. Tapestry; originally invented to hide the coarseness of the walls of a chamber. Different materials were employed for this purpose, some of them exceedingly costly and beautifully worked in figures, gold and silk.

Hatching. Drawing parallel lines close together for the purpose of indicating of a section of anything. The lines are generally drawn at an angle of 45° with a horizontal.

Haunches. The sides of an arch, about half-way from the springing to the crown.

Headers. In masonry, are stones or bricks extending over the thickness of a wall. In carpentry, the large beam into which the common joists are framed in framing openings for stairs, chimneys, etc.

Heading Courses. Courses of a wall in which the stone or brick are all headers.

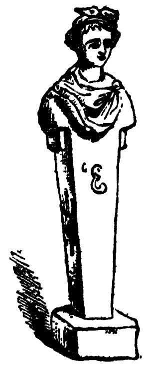
Head-way. Clear space or height under an arch, or over a stairway, and the like.

Heel. Of a rafter, the end or foot that rests upon the wall plate.

Height. Of an arch, a line drawn from the middle of the chord to the intrados.

Helix. A small volute or twist like a stalk, representing the twisted tops of the acanthus, placed under the abacus of the Corinthian capital.

Hermes. A rough quadrangular stone or pillar, having a head, usually of Hermes or Mercury, sculptured on the top, without arms or body, placed by the Greeks in front of buildings.



HERMES

Herring-bone Work. Bricks, tile, or other materials arranged diagonally in building.

Hexastyle. A portico of six columns in front is of this description.

High Altar. The principal altar in a cathedral or church. Where there is a second, it is generally at the end of the choir or chancel, not in the lady chapel.

Hip-knob. The finial on the hip of a roof, or between the barge boards of a gable.

Hip-roof. A roof which rises by equally inclined planes from all four sides of the building.

Hippodrome. A place appropriated by the ancients for equestrian exercises.

Hips. Those pieces of timber placed in an inclined position at the corners or angles of a hip-roof.

Hood-mold. A word used to signify the drip-stone for label over a window or door opening, whether inside or out.

Hors Coucours. (Fr.) Disqualification from competition.

Hôtel de Ville. The town-hall, or guild-hall, in France, Germany, and Northern Italy. The building, in general, serves for the administration of justice, the receipt of town dues, the regulation of markets, the residence of magistrates, barracks for police, prisons, and all other fiscal purposes. As may be imagined, they differ very much in different towns, but they have almost invariably attached to them or closely adjacent, a large clock-tower containing one or more bells, for calling the people together on special occasions.

Hôtel Dieu. The name for a hospital in mediæval times. In England there are but few remains of these buildings, one of which is at Dover; in France there are many. The most celebrated is the one of Angers, described by Parker. They do not seem to differ much in arrangement of plan from those in modern days, the accommodation for the chaplain, medicine, nurses, stores, etc., being much the same in all ages, except that in some of the earlier, instead of the sick being placed in long wards like galleries, as is now done, they occupied large buildings, with naves and side aisles, like churches.

Housing. The space taken out of one solid to admit the insertion of another. The base on a stair is generally housed into the treads and risers; a niche for a statue.

Hypæthros. A temple open to the air, or uncovered. The term may be the more easily understood by supposing the roof removed from over the nave of a church in which columns or piers go up from the floor to the ceiling, leaving the aisles still covered.

Hypogea. Constructions under the surface of the earth, or in the sides of a hill or mountain.

Ichnography. A horizontal section of a building or other object, showing its true dimensions according to a geometric scale, a ground plan.

Impluvium. The central part of an ancient Roman court, which was uncovered.

Impost. A term in classic architecture for the horizontal moldings of piers or pilasters, from the top of which spring the archivolts or moldings which go round the arch.

In Antis. When there are two columns between the antæ of the lateral walls and the cella.

Inca Architecture. The architecture of the pre-Columbian inhabitants of Peru and neighboring countries.

Incise. To cut in; to carve; to engrave.

Indented. Toothed together.

India, Architecture of. That of the great peninsula bounded on the north by the Himalaya mountains, and reaching from the lower Ganges on the east to the frontiers of Afghanistan on the west. The history of architecture in this region presents many difficult problems, especially as to its origin and early periods. The natural divisions of the art, as of the civilization of India follow religious lines. They comprise the Buddhist, the Jaina, the Brahman, the Mohammedan or Indo-Moslem Styles. A predilection for minute and profuse ornament covering every part of the architecture is a characteristic common to all the divisions. The second characteristic is the multiplication of horizontal bands and lines, giving an appearance as of stratification even to towers and minarets. A third characteristic is the indefinite reduplication and multiplication of the same motive, which is often itself a miniature of the tower or other construction of which it is a part. Lastly, it should be observed that, in Hindu design generally, the dominant masses and chief features of a building are in no wise evolved out of structural requirements, but are purely artistic creations, in which fancy and tradition both have had a share. Modern architecture of India is following the old traditions even with the many buildings which have been erected under the British rule.

Inlaying. Inserting pieces of ivory, metal, or choice woods, or the like, into a groundwork of some other material, for ornamentation.

Insulated. Detached from another building. A church is insulated, when not contiguous to any other edifice. A column is said to be insulated, when standing free from the wall; thus, the columns of peripteral temples were insulated.

Intaglio. A sculpture or carving in which the figures are sunk below the general surface, such as a seal the impression of which in wax is in bas-relief; opposed to Cameo.

Intercolumniation. The distance from column to column, the clear space between columns.

Interlaced Arches. Arches where one passes over two openings, and they consequently cut or intersect each other.

Intrados. Of an arch, the inner or concave curve of the arch stones.

Inverted Arches. Those whose key-stone or brick is the lowest in the arch.

Ionic Order. One of the orders of Classical architecture.

Iron Work. In mediæval architecture, as an ornament, is chiefly confined to the hinges, etc., of doors and of church chests, etc. In some instances not only do the hinges become a mass of scroll work, but the surface of the doors is covered by similar ornaments. In almost all styles the smaller and less important doors had merely plain strap hinges, terminating in a few bent scrolls, and latterly in fleur-de-lis. Escutcheon and ring handles, and the other furniture, partook more or less of the character of the time. On the Continent of Europe the knockers are very elaborate. At all periods doors have been ornamented with nails having projecting heads, sometimes square, sometimes polygonal, and sometimes ornamented with roses, etc. The iron work of windows is generally plain, and the ornament confined to simple fleur-de-lis heads to the stanchions. The iron work of screens enclosing tombs and chapels is noticed under *Grille*, *q.v.*

Ireland, Architecture of. Ireland has preserved vestiges of architectural forms which have almost disappeared from Europe. In her own Gaelic she has curious records of builders' methods in osier, wattle, wood and stone. The Irish did not use mortar, for the stones were carried away for other uses upon abandonment. The outer walls of forts and houses, however, were whitewashed. The beehive huts and round towers are the only distinctive architecture handed down by the ancient Irish. There are many modern picturesque churches, city halls, merchants' houses, abbeys, cathedrals, castles, and ruins of forts and monasteries.

Italian Architecture. The architecture of Italy; more especially that of any style assumed to have taken its origin in Italy. The term is used carelessly with the especial significance of a neoclassic style of great severity and of systematic design and fixed proportion, as if of the Italian sixteenth century. The term also refers to the architecture of the continental part of the kingdom of Italy together with San Marino. All this region is rich in ancient architecture, architectural sculpture, mosaic, and in portable works of art of durable material; also in painting of epochs, beginning with the thirteenth century and with a few remains of early painting. Here are Italian pre-Roman structures with those of Etruscan and Oscan remains of unique value. Grecian architecture of Italy is of peculiar importance. At the same time the historical buildings of Rome are the foundations of our knowledge of this most important epoch in building—the root and stem of all modern European architecture. Latin architecture can be studied only in Italy. There is no country in Europe in which so wide a field of art exists as in Italy, nor any country in the world in which so many styles, each representative and peculiar, are to be seen and studied, side by side.

Jack. An instrument for raising heavy loads, either by a crank, siren and pinion, or by hydraulic power, and in all cases worked by hand.

Jack Rafter. A short rafter, used especially in hip-roofs.

Jamb. The side-post or lining of a doorway or other aperture. The jambs of a window outside the frame are called Reveals.

Jamb-shafts. Small shafts to doors and windows with caps and bases; when in the inside arris of the jamb of a window they are sometimes called Esconsons.

Japan, Architecture of. That of the modern state of that name, and chiefly of the southern islands. Previous to the coming of the first Buddhist priests from Korea in A.D. 552, we know nothing of the architecture of Japan. At that time the islands lay in almost complete barbarism and the efforts at shelter were characteristic of a mingling of Tartar and Malay blood with the primitive

stock. Traces of this primitive mode may be found in the modern Shinto temples, where grotesque attempts at ornament and the preservation of tradition still remain. In 593 when Buddhist priests, architects, scholars and teachers were invited into the country from Korea, the architectural style introduced, already perfectly developed in China, was seized upon by the Japanese and made their own. The buildings are architecturally beautiful solely because of the subtlety of their proportions, dignity of composition, amazing refinement of line, and vitality of curves that characterize them. With the transferring of the capital to Kyoto the second period of Japanese civilization and art began. In architecture the purest Chinese models were followed, while architectural decoration became amazingly rich and splendid. A kind of palace pavilion at Uji, built in 1052, in subtle grace, perfection of curves and refinement of composition, touches the highest point in Japanese architecture. Two centuries of civil conflict and martial activity succeeded this epoch of culture. This was followed by the Kamakura period and, though painting was the favorite mode of artistic expression, architecture reached the last phase of greatness before the first trace of decay showed itself. For two hundred and twenty-five years, in the seventeenth century, when Japan was closed to the world, a great period of industrial development and steady progressing civilization unhampered by wars ensued. It is only in their domestic work that the traditions of true architecture remain.

Joggle. A joint between two bodies so constructed by means of jogs or notches as to prevent their sliding past each other.

Joinery. That branch in building confined to the nicer and more ornamental parts of carpentry.

Joist. A small timber to which the boards of a floor or the laths of ceiling are nailed. It rests on the wall or on girders.

Keep. The inmost and strongest part of a mediæval castle, answering to the citadel of modern times. The arrangement is said to have originated with Gundulf, the celebrated Bishop of Rochester. The Norman keep is generally a very massive square tower, the basement or stories partly below ground being used for stores and prisons. The main story is generally a great deal above ground level, with a projecting entrance, approached by a flight of steps and drawbridge. This floor is generally supposed to have been the guard-room or place for the soldiery; above this was the hall, which generally extended over the whole area of the building, and is sometimes separated by columns; above this are other apartments for the residents. There are winding staircases in the angles of the buildings, and passages and small chambers in the thickness of the walls. The keep was intended for the last refuge, in case the outworks were scaled and the other buildings stormed. There is generally a well in a mediæval keep, ingeniously concealed in the thickness of a wall, or in a pillar. The most celebrated of Norman times are the White Tower in London, the castles at Rochester, Arundel, Newcastle, Castle Hedingham, etc. The keep was often circular.

Key-stone. The stone placed in the center of the top of an arch. The character of the key-stone varies in different orders. In the Tuscan and Doric it is only a simple stone projecting beyond the rest; in the Ionic it is adorned with moldings in the manner of a console; in the Corinthian and Composite it is a rich sculptured console.

King-post. The middle post of a trussed piece of framing for supporting the tie-beam at the middle and the lower ends of the struts.

Knee. A piece of timber naturally or artificially bent to receive another to relieve a weight or strain.

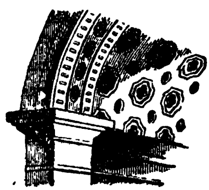
Knob, Knot. The bunch of flowers carved on a corbel, or on a Boss.

Kremlin. The Russian name for the citadel of a town or city.

Label. Gothic: the drip or hood-molding of an arch, when it is returned to the square.

Label Terminations. Carvings on which the labels terminate near the springing of the windows. In Norman times those were frequently grotesque heads of fish, birds, etc., and sometimes stiff foliage. In the Early English and Decorated periods they are often elegant knots of flowers, or heads of kings, queens, bishops, and other persons supposed to be the founders of churches. In the Perpendicular period they are often finished with a short square, mitred return or knee, and the foliages are generally leaves of square or octagonal form.

Lacunar. A paneled or coffered ceiling or soffit. The panels or cassoons of a ceiling are by Vitruvius called lacunaria.



LACUNARS IN CEILING

Lady-chapel. A small chapel dedicated to the Virgin Mary, generally found in ancient cathedrals.

Lancet. A high and narrow window pointed like a lancet, often called a lancet window.

Landing. A platform in a flight of stairs between two stories; the terminating of a stair.

Lantern. A turret raised above a roof or tower and very much pierced, the better to transmit light. In modern practice this term is generally applied to any raised part in a roof or ceiling containing vertical windows, but covered in horizontally. The name was also often applied to the louver or femerall on a roof to carry off the smoke; sometimes, too, to the open constructions at the top of towers, as at Ely Cathedral, probably because lights were placed in them at night to serve as beacons.

Lanterns of the Dead. Curious small slender towers, found chiefly in the center and west of France, having apertures at the top, where a light was exhibited at night to mark the place of a cemetery. Some have supposed that the round towers in Ireland may have served for this purpose.

Lath. A slip of wood used in slating, tiling, and plastering.

Latin Architecture. The early Christian architecture of historic Europe. It is reasonably called Latin, because it was the architecture of the Latin Church, and was developed among the Latin races of Italy. From Italy it passed into Gaul, Germany, and probably into Spain, and even Britain. Beginning with Constantine, it held its place from the fourth century to the eighth, and only in the ninth began to give way to Romanesque, which grew up under the impulse of the Teutonic races, and which, displacing it, was the architecture of the Western Church from the tenth century till the end of the twelfth. The earliest Christian Churches started with the simple outlines of the basilicas. Another family of Latin Churches was round or polygonal, and often surrounded by an aisle. The form that grew out of this by the addition of four arms of a cross naturally led to a square center, over which a dome was set almost from the beginning. The only ornament of the early churches was in their altars and the surrounding furniture, which were lavishly enriched, and in the pictorial decoration of their surfaces. The chief of this was mosaic, which began at Constantinople, spread to Ravenna, and became the one

artistic achievement of Rome, where in Italy it centered. It was applied first to the apses; in the richer churches it was spread over the interior walls, and in a simpler ornamental form over the floors. When mosaic could not be had, or was too costly, painting was habitually substituted; the interiors were brilliant with Bible stories and legends of the Church. In many this decoration overflowed upon the outside, and the fronts, usually smoothly stuccoed over, were covered with mosaic or painting.

Lattice. Any work of wood or metal made by crossing laths, rods, or bars, and forming a net-work. A reticulated window, made of laths or slips of iron, separated by glass windows, and only used where air rather than light is to be admitted, as in cellars and dairies.

Lavabo. The lavatory for washing hands, generally erected in cloisters of monasteries. A very curious one at Fontenay, surrounding a pillar, is given by Viollet-le-Duc. In general, it is a sort of trough, and in some places has an almry for towels, etc.

Lavatory. A place for washing the person.

Lean-to. A small building whose rafters pitch or lean against another building, or against a wall.

Lectern. The reading-desk in the choir of churches.

Ledge, or Ledgement. A projection from a plane, as slips on the side of window and door frames to keep them steady in their places.

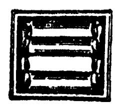
Ledgers. The horizontal pieces fastened to the standard poles or timbers of scaffolding raised around buildings during their erection. Those which rest on the ledgers are called putlogs, and on these the boards are laid.

Lewis. An iron clamp dovetailed into a large stone to lift it by.

Lich-gate. A covered gate at the entrance of a cemetery, under the shelter of which the mourners rested with the corpse, while the procession of the clergy came to meet them. There are several examples in England.

Light. A division or space in a sash for a single pane of glass; also a pane of glass.

Linen Scroll. An ornament formerly used for filling panels, and so called from its resemblance to the convolutions of a folded napkin.



LINEN SCROLL

Lining. Covering for the interior, as casing is covering for the exterior surface of a building; also, such as linings of a door for windows, shutters, and similar work.

Lintel. The horizontal piece which covers the opening of a door or window.

Lip Mold. A molding of the Perpendicular period like a hanging lip.

List, or Listel. A little square molding, to crown a larger; also termed a fillet.

Lithograph. A print from a drawing on stone.

Lobby. An open space surrounding a range of chambers, or seats in a theater; a small hall or waiting room.

Lodge. A small house in a park.

Loft. The highest room in a house, particularly if in the roof; also, a gallery raised up in a church to contain the rood, the organ, or singers.

Loggia. An outside gallery or portico above the ground, and contained within the building.

Lombard Architecture. A name given to the round-arched architecture of Italy, introduced by the conquering Goths and Ostrogoths, and which superseded the Romanesque. It reigned between the eighth and twelfth centuries, during the time that the Saxon and Norman styles were in vogue in England, and corresponded with them in its development into the Continental Gothic.

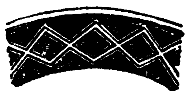
Loop-hole. An opening in the wall of a building, very narrow on the outside and splayed within, from which arrows or darts might be discharged on an enemy. They are often in the form of a cross, and generally have round holes at the ends.

Lotus. A plant of great celebrity among the ancients, the leaves and blossoms of which generally form the capitals of Egyptian columns.

Louver. A kind of vertical window, frequently in the peaks of gables, and in the top of towers, and provided with horizontal slats which permit ventilation and exclude rain.

Lozenge Molding. A kind of molding used in Norman architecture, of many different forms, all of which are characterized by lozenge-shaped ornaments

Lunette. The French term for the circular opening in the groining of the lower stories of towers, through which the bells are drawn up.



LOZENGE MOLDING

LOUVER WINDOW

Machicolation. A parapet or gallery projecting from the upper part of the wall of a house or fortification, supported by brackets or corbels, and perforated in the lower part so that the defenders of the building might throw down darts, stones, and sometimes hot sand, molten lead, etc.; upon their assailants below.

Man-hole. A hole through which a man may creep into a drain, cesspool, steam-boiler, etc.

Manor-house. The residence of the suzerain or lord of the manor; in France the central tower or keep of a castle is often called the *manoir*.

Mansard Roof. Curb roof, invented by François Mansard, a distinguished French architect, who died in 1666.

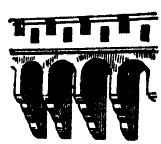
Mansion. A residence of considerable size and pretension.

Mantel. The work over a fireplace in front of a chimney; especially, a shelf, usually ornamented, above the fireplace.

Marquetry. Inlaid work of fine hard pieces of wood of different colors, also of shells, ivory, and the like.

Mausoleum. A magnificent tomb or sumptuous sepulchral monument.

Maya Architecture. The architecture of the pre-Columbian inhabitants of Yucatan and adjacent regions.



MACHICOLATION

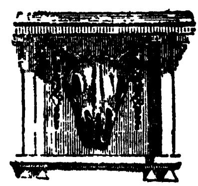
Medallion. Any circular tablet on which are embossed figures or busts.

Mediæval Architecture. The architecture of England, France, Germany, etc., during the Middle Ages, including the Norman and Early Gothic styles. It comprises also the Romanesque, Byzantine and Saracenic, Lombard, and other styles.

Members. The different parts of a building, the different parts of an entablature, the different moldings of a cornice, etc.

Merlon. That part of a parapet which lies between two embrasures.

Mesopotamia, Architecture of. That of the great plain between the rivers Tigris and Euphrates, which was the seat of a civilization which is perhaps as ancient as that of Egypt. The countries in which developed these two most ancient civililzations are in many respects strikingly similar. The southern portion of the Mesopotamia plain is Chaldea; its principal cities in the earliest times were Ur and Larsam, and later the more northerly Babylon. The northern portion of the plain is Assyria, whose capital in earliest times was Assur, and later Nineveh. (1) *Chaldean or Babylonian:* The absence of stone forced builders to the development of brick construction. The temples seem to have been vast stepped pyramids, rising sometimes to a height comparable to that of the great Egyptian pyramids, if not higher, with a shrine at the top. The palaces were erected on great platforms, and consisted of a collection of apartments about courtyards. (2) *Assyrian:* Although building in a more hilly country the Assyrians still continued to raise their palaces upon platforms of earth or crude brick as did the Chaldeans; but they faced these mounds with retaining walls of massive cut stone easily obtained and brought down the Tigris from the neighboring mountains. Their temples seem to have been similar in character to, though smaller in scale than, the Babylonian temples. That the Assyrian builders were thoroughly familiar with the vault is clear, from the city gates and the vaulted drains beneath the palaces. If a method of vault construction was used, as seems probable, it becomes easier to explain the existence of the great vaults of similar construction in Persia; and we get a glimpse of a continuous history of vault construction in the East from the time of the Assyrian to the time of the Byzantine empire; a system of construction radically different from that employed in the West.



METOPE

Metope. The square recess between the triglyphs in a Doric frieze. It is sometimes occupied by sculptures.

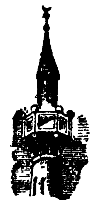
Mexico, Architecture of. That of the Republic as it has existed since 1854. *Pre-Columbian:* Within the borders of Mexico is contained almost the entire range of aboriginal American architecture. At one end of the scale are shelters of the rudest kind, and at the other the really extraordinary stone ruins of Yucatan. In the wide intervals are cliff dwellers, houses of jacál, of pisé, of cajon, and of adobe bricks. In their own way, ethnologically, archæologically, and artistically, they are of surpassing interest, exhibiting, as they do, one of the most extraordinary race developments of the world. It is fairly well established that the strictly Aztec structures are comparatively modern. *Modern:* The architecture of Mexico has been developed in a dry equable climate, necessitating protection from the sun rather than from cold or rain, by a race which mingles the polish and traditions of Europe with the barbaric taste of the Indian. Although stone serves for the best work, a native clay is most commonly used; as sun-dried brick it is known as adobe; it further serves when kiln-dried as terra-cotta ornament, roofing tiles, brick, etc., and colored glazed tile are also made of it. It is often applied to masonry in the form of stucco and plaster, and such walls are frequently covered with colored washes. Wrought iron in the form of balconies and grilles is common, but wood is scarce, and rarely used in building. The work is unique in its boldness of color and outline, as shown in its churches, patios, portals, markets, government buildings, fountains, and aqueducts.

Mezzanine. A low story between two lofty ones. It is called by the French *entresol,* or inter-story.

Mezzo-rilievo. Or mean relief, in comparison with alto-rilievo, or high relief.

Minaret. Turkish: a circular turret rising by different stages or divisions, each of which has a balcony.

Minster. Probably a corruption of monasterium — the large church attached to any ecclesiastical fraternity. If the latter be presided over by a bishop, it is generally called a Cathedral; if by an abbot, an Abbey; if by prior, a Priory.



MINARET

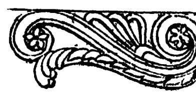
Minute. The sixtieth part of the lower diameter of a column; it is the measure used by architects to determine the proportions of an order.

Miserere. A seat in a stall of a large church made to turn up and afford support to a person in a position between sitting and standing. The under side is generally carved with some ornament, and very often with grotesque figures and caricatures of different persons.

Mission Architecture. Pertaining to a building or group of buildings composing a frontier or outpost settlement of one of the Spanish religious orders in America. At first these missions were rude huts, but they developed into extensive structures in the form of a quadrilateral building surrounding a court. There were churches, hospitals, workshops,. schoolrooms, etc. They were of simple outline with artistic masses. Large stone basins, which serve as fountains, are commonly found in the cloisters or near the entrance doorways of the missions.

Miter. A molding returned upon itself at right angles is said to miter. In joinery, the ends of any two pieces of wood of corresponding form, cut off at 45°, necessarily abut upon one another so as to form a right angle, and are said to miter.

Modillion. So called because of its arrangement in regulated distances; the enriched block or horizontal bracket generally found under the cornice of the Corinthian entablature. Less ornamented, it is sometimes used in the Ionic.



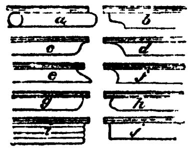
MODILLION

Module. This is a term which has been generally used by architects in determining the relative proportions of the various parts of a columnar ordinance. The semi-diameter of the column at its base is the module, which, being divided into thirty parts called minutes, any part of the composition is said to be of so many modules and minutes, or minutes alone, in height, breadth or projection. The whole diameter is now generally preferred as a module, it being a better rule of proportion than its half.

Mogul Architecture. (1) The architecture of the Mogul dynasty. This was established in northwest India in the sixteenth century. The characteristics are very different from those of the purely Indian styles. (2) Loosely, and because of the little study which the Mohammedan architecture in India has received, any architecture of Mohammedan races or dynasties in India.

Molding. When any work is wrought into long regular channels or projections, forming curves or rounds, hollows, etc., it is said to be molded, and each separate member is called a molding. In mediæval architecture the principal

moldings are those of the arches, doors, windows, piers, etc. In the Early English style, the moldings, for some time, formed groups set back in squares, and frequently very deeply undercut. The scroll molding is also common. Small fillets now become very frequent in the keel moldings, from its resemblance in section to the bottom of a ship; sometimes, also, it has a peculiar hollow on each side, like two wings. Later in the Decorated style the moldings are more varied in design, though hollows and rounds still prevail. The undercutting is not so deep, fillets abound, ogees are more frequent, and the wave mold, double ogee, or double ressaunt, is often seen. In many places the strings and labels are a round, the lower half of which is cut off by a plain chamfer. The moldings in the later styles in some degree resemble those of the Decorated, flattened and extended; they run more into one another, having fewer fillets, and being, as it were, less grouped. One of the principal features of the change is the substitution of one, or perhaps two (seldom more), very large hollows in the set of moldings. These hollows are neither circular nor elliptical, but obovate, like an egg cut across, so that one half is larger than the other. The brace mold also has a small bead, where the two ogees meet. Another sort of molding, which has been called a lip mold, is common in parapets, bases, and weatherings.



MOLDINGS

a, astragal; *b*, ogee; *c*, cymatium; *d*, cavetto; *e*, scotia, or casement; *f*, apophyges; *g*, ovolo, or quarter round; *h*, torus; *i*, reeding; *j*, band.

Moldings, Ornamented. The Saxon and early Norman moldings do not seem to have been much enriched, but the complete and later styles of Norman are remarkable for a profusion of ornamentation, the most usual of which is what is called the zigzag. This seems to be to Norman architecture what the meander or fret was to the Grecian; but it was probably derived from the Saxons, as it is very frequently found in their pottery. Bezants, quatrefoils, lozenges, crescents, billets, heads of nails, are very common ornaments. Besides these, battlements, cables; large ropes round which smaller ropes are turned, or, as our sailors say, " wormed "; scallops, pellets, chains, a sort of conical barrels, quaint stiff foliages, beaks of birds, heads of fishes, ornaments of almost every conceivable kind, are sculptured in Norman moldings; and they are used in such profusion as has been attempted in no other style. The decorations on Early English moldings are chiefly the dog-tooth, which is one of the great characteristics of this style, though it is to be found in the Transition Norman. It is generally placed in a deep hollow between two projecting moldings, the dark shadow in the hollow contrasting in a very beautiful way with the light in these moldings. In this period and in the next the tympanum over doorways, particularly if they are double doors, is highly ornamented. Those of the Decorated period resemble the former, except that the foliage is more natural and the dog-tooth gives way to the ball-flower. Some of the hollows, also, are ornamented with rosettes set at intervals, which are sometimes connected by a running tendril, as the ball-flowers are frequently. Some very pleasing leaf-like ornaments in the labels of windows are often found in Continental architecture. In the Perpendicular period the moldings are ornamented very frequently by square four-leaved flowers set at intervals, but the two characteristic ornaments of the time are running patterns of vine leaves, tendrils, and grapes in the hollows, which by old writers are called

"vignettes in casements," and upright stiff leaves, generally called the Tudor leaf. On the Continent moldings partook much of the same character.

Monastery. A set of buildings adapted for the reception of any of the various orders of monks, the different parts of which are described in the separate article, *Abbey.*

Monastic Architecture. The architecture of religious organizations having permanent rules of conduct and life, and divided into considerable bodies of men or women who devote themselves in common to a life of worship and labor. Many religions have recognized these religious bodies which, when in Christian nations, are called Orders of Monks and of Nuns; terms which are used also in an extended sense as applicable to similar communities in other religions.

Monotriglyph. The intercolumniations of the Doric order are determined by the number of triglyphs which intervene, instead of the number of diameters of the column, as in other cases; and this term designates the ordinary intercolumniation of one triglyph.

Moorish Architecture. The architecture of the Mohammedan races of North Africa and of the Kindgoms which they established in Spain. The work of these last-named states may be designated Hispano-Moresque.

Mosaic. Pictorial representations, or ornaments, formed of small pieces of stone, marble, or enamel of various colors. In Roman houses the floors are often entirely of mosaic, the pieces being cubical. The best examples of mosaic work are found in St. Mark's, at Venice.

Moslem Architecture. The architecture of the Mohammedans, particularly of the Arab conquerors in Syria and Egypt, of the Moors in North Africa and Spain, of the Persians, of the Mohammedans of India, and of the Turks. Except in Persia, Moslem architecture has everywhere begun with Christian models. The Arabs who conquered the Mediterranean littoral in the seventh century were no artists; neither were the Osmauli Turks, nor the Moguls who overran India and Persia. Bringing with them no artistic traditions and no established types, they employed Coptic, Syrian, Greek and Byzantine builders to erect and decorate their mosques and palaces in the prevailing local styles. Civilized in time by their contact with the Western world, they developed, in the course of the centuries, decided predilections and aptitudes in design, by which their art was given a form and spirit wholly unlike those of the arts on which it was based, emphatically Oriental in character. Moslem architecture started under Arab dominion, early in the seventh century.

Mosque. A Mahometan temple, or place of worship.

Mullion, Munion. The perpendicular pieces of stone, sometimes like columns, sometimes like slender piers, which divide the bays or lights of windows or screen-work from each other. In all styles, in less important work, the mullions are often simple plain chamfered, and more commonly have a very flat hollow on each side. In larger buildings there is often a bead or boutell on the edge, and often a single very small column with a capital. As tracery grew richer, the windows were divided by a larger order of mullion, between which came a lesser or subordinate set of mullions, which ran into each other. The term is also applied to a wood or iron division between two windows.

Multifoil. A leaf ornament consisting of more than five divisions, applied to foils in windows.

Muntin. A small, slender mullion in light framing, as a sash bar, a middle stile of a door.

Mutule. The rectangular impending block under the corona of the Doric cornice, from which guttæ or drops depend. Mutule is equivalent to modillion but the latter term is applied more particularly to enriched blocks or brackets, such as those of Ionic and Corinthian entablatures.

Narthex. The long arcaded porch forming the entrance into the Christian basilica. Sometimes there was an inner narthex, or lobby, before entering the church. When this was the case, the former was called exo-narthex, and the latter eso-narthex. In the Byzantine churches this inner narthex forms part of the solid structure of the church, being marked off by a wall or row of columns, whereas in the Latin churches it was usually formed only by a wooden or other temporary screen.

Natural Beds. In stratified rocks, the surface of a stone as it lies in the quarry. If not laid in walls in their natural bed the laminæ separate.

Nave. The central part between the arches of a church, which formerly was separated from a chancel or choir by a screen. It is so called from its fancied resemblance to a ship. In the nave were generally placed the pulpit and font. In continental Europe it often also contains a high altar, but this is of rare occurrence in England.

Necking. The annulet or round, or series of horizontal moldings, which separate the capital of a column from the plain part or shaft.

Neoclassic Architecture. The architecture of modern times, beginning with the Italian Renaissance of the fifteenth century; and especially that which is carefully studied from Greco-Roman examples.

Netherlands, Architecture of. The architecture of the low-lying country at the mouth of the Rhine, where this river and the Meuse unite, and also divide and subdivide into many branches. Its common name among foreigners is Holland, which is properly the name of the largest and wealthiest of the little states of which it was formerly composed. The country inevitably followed closely the immensely powerful impulse given by the architecture of the French lands lying not far to the south. The Protestant Reformation, which in the sixteenth century divided the state as above described from Belgium, came too late to affect the growth of architecture in those styles which were swayed by religious enthusiasm. The Dutch seventeenth century architecture is unique and altogether national in character, owing to mingled influences of domestic feeling and the northern climate. The attraction in all the country is nearly the same as in Amsterdam, namely, the fascinating private houses, town halls, weighing houses, etc. For the study of architecture, domestic and civic of the simpler kind, no country in Europe surpasses the Netherlands.

Newel. In mediæval architecture, the circular ends of a winding staircase which stand over each other, and form a sort of cylindrical column.

Newel Post. The post, plain or ornamented, placed at the first, or lowest step, to receive or start the hand-rail upon.

Niche. A recess sunk in a wall, generally for the reception of a statue. Niches sometimes terminate by a simple label, but more commonly by a canopy, and with a bracket or corbel for the figure, in which case they are often called tabernacles.

Norman Style. Was that species of Romanesque which was practised by the Normans, and which was introduced and fully developed in England after they had established themselves in it. The chief features of this style are plainness and massiveness. The arches, windows, and doorways were semi-

circular, the pillars were very massive, and often built up of small stones laid like brickwork.

Norse American Architecture. The architecture in the western hemisphere which shows Scandinavian influence. A few examples of early Norse buildings are found in ruins in southern Greenland, and there are traces in Labrador.

North African Architecture. The architecture of the vast tract of country bordering on the Mediterranean, comprising Tripoli, Tunisia, Algeria, and Morocco.

Nosings. The rounded and projecting edges of the treads of a stair, or the edge of a landing.

Obelisk. Lofty pillars of stone, of a rectangular form, diminishing toward the top, and generally ornamented with inscriptions and hieroglyphics among the ancient Egyptians.

Observatory. A building erected on an elevated spot of ground for making astronomical observations.

Octostyle. A portico of eight columns in front.

Offsets. When the face of a wall is not one continued surface, but sets in by horizontal jogs, as the wall grows higher and thinner, the jogs are called offsets.

Ogee. The name applied to a molding, partly a hollow and partly a round, and derived no doubt from its resemblance to an O placed over a G. It is found in Norman work, and is not very common in Early English. It is of frequent use in Decorated work, where it becomes sometimes double, and is called a wave molding; and later still, two waves are connected with a small bead, which is then called a brace molding. In ancient MSS. it is called a Ressaunt.

Orchestra. In ancient theaters, where the chorus used to dance; in modern theaters, where the musicians sit.

Order. A column with its entablature and stylobate is so called. The term is the result of the dogmatic laws deduced from the writings of Vitruvius, and has been exclusively applied to those arrangements which they were thought to warrant.

Oriel Window. Gothic: a projecting angular window, commonly of a trigonal or pentagonal form, and divided by mullions and transoms into different bays and compartments.

Orthography. A geometrical elevation of a building or other object in which it is represented as it actually exists or may exist, and not perspectively, or as it would appear.

Orthostyle. A columnar arrangement in which the columns are placed in a straight line.

Ovolo. Same as *Echinus*.

Oylet. A small hole, an eyelet.

Pagoda. A name given to temples in India and China.

Palace. The dwelling of a king, prince, or bishop.

Pale. A fence picket, sharpened at the upper end.

Palladian Architecture. Relating to the art or style of Palladio. This work belonged to the period of decline in Italian neoclassic architecture, when classic formality and the punctilious observance of rules were taking the place of the grace, freedom, and life which characterized the earlier period. The classicism of Palladio was noted for a certain cold and correct purity of

form. A favorite motive of his, known as the Palladian Motive, was the use of a minor and major order of columns in the same composition, the former supporting the arches which occurred between the latter, as in his two-storied arcade about the mediæval basilica of Vicenza. His writings had the good fortune to be considered the most authoritative expositions of the principles of classic architecture in the seventeenth and eighteenth centuries throughout Europe, and his monuments were models for the classic art of that period; the name Palladian, therefore, is descriptive of that variety of neoclassic architecture distinguished for cold, inelastic, and unimaginative, but correct, elegant, and studied classicism. It is generally held as true that the English classical revivalists followed Palladio, whereas the French were rather under the influence of Vignola. *Andrea Palladio, Architect:* born about 1518; died August, 1580.

Pane. Probably a diminutive of panneau, a term applied to the different pieces of glass in a window; same as *Light.*

Panel. Properly a piece of wood framed within four other pieces of wood, as in the styles and rails of a door, filling up the aperture, but often applied both to the whole square frame and the sinking itself; also to the ranges of sunken compartments in wainscoting, cornices, corbel tables, groined vaults, ceilings, etc.

Pantograph, or **Pentagraph.** An instrument for copying on the same, or an enlarged or reduced scale.

Pantry. An apartment or closet in which bread and other provisions are kept.

Papier-maché. A hard substance made of a pulp from rags or paper mixed with size or glue, and molded into any desired shape. Much used for architectural ornaments.

Parapet. A dwarf wall along the edge of a roof, or round a terrace walk, etc., to prevent persons from falling over, and as a protection to the defenders in case of a siege. Parapets are either plain, embattled, perforated, or paneled. The last two are found in all styles except the Norman. Plain parapets are simply portions of the wall generally overhanging a little, with coping at the top and corbel table below. Embattled parapets are sometimes paneled, but oftener pierced for the discharge of arrows, etc. Perforated parapets are pierced in various devices—as circles, trefoils, quatrefoils and other designs—so that the light is seen through. Paneled parapets are those ornamented by a series of panels, either oblong or square, and more or less enriched, but are not perforated. These are common in the Decorated and Perpendicular periods.

Pargeting. A species of plastering decorated by impressing patterns on it when wet. These seem generally to have been made by sticking a number of pins in a board in certain lines or curves, and then pressing on the wet plaster in various directions, so as to form geometrical figures. Sometimes these devices are in relief, and in the time of Elizabeth represent figures, birds, foliages, etc. Rough plastering, commonly adopted for the interior surface of chimneys.

Parging. Thin coat of plastering to smooth off rough brick or stone walls.

Parlor. A room in a house which the family usually occupy for society and conversation, and for receiving visitors. The apartment in a monastery or nunnery where the inmates are permitted to meet and converse with each other, or with visitors and friends from without.

Parochial. Belonging or relating to a parish.

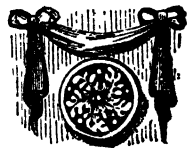
Parquetry, or **Marquetry.** A kind of inlaid floor composed of small pieces of wood either square or triangular, which are capable of forming, by their disposition, various combinations of figures; this description of joinery is very suitable for the floors of libraries, halls, and public apartments.

Parthian Architecture. The architecture of the peoples subjected to the Parthian dynasty, which lasted for nearly five centuries, from 250 B.C. to A.D. 226. The Parthians were not a building race, but details unearthed of various decorative features with the remains of palaces and temples help to reconstruct parts of these buildings, with the vaulted rooms and the carvings of the sun god, moon, bulls' heads and griffins at the entrances.

Parti. (Fr.) Scheme.

Party Walls. Partitions of brick or stone between buildings on two adjoining properties.

Patera. A circular ornament resembling a dish, often worked in relief on friezes, etc.



PATERA

Pavilion. A turret or small insulated building, and comprised beneath a single roof; also, the projecting part in front of a building which marks the center, and which sometimes flanks a corner, when it is termed an angular pavilion.

Pedestal. The square support of a column, statue, etc., and the base or lower part of an order of columns; it consists of a plinth for a base, the die, and a talon crowned for a cornice. When the height and width are equal, it is termed a square pedestal; one which supports two columns, a double pedestal; and if it supports a row of columns without any break, it is a continued pedestal.

Pediment. A low triangular crowning, ornamented, in front of a building, and over doors and windows. Pediments are sometimes made in the form of a segment; the space enclosed within the triangle is called the tympanum. Also, the gable ends of classic buildings, where the horizontal cornice is carried across the front, forming a triangle with the end of the roof.

Pendent. A name given to an elongated boss, either molded or foliated, such as hang down from the intersection of groins, especially in fan tracery, or at the end of hammer beams. Sometimes long corbels, under the wall pieces, have been so called. The name has also been given to the large masses depending from enriched ceilings, in the later works of the Pointed style.

Pendent Posts. A name given to those timbers which hang down the side of a wall from the plate in hammer beam trusses, and which receive the hammer braces.

Pendentive. A name given to an arch which cuts off, as it were, the corners of a square building internally, so that the superstructure may become an octagon or a dome. In mediæval architecture these arches, when under a spire in the interior of a tower, are called Squinches.

Pendentive Bracketing, or **Cove Bracketing.** Springing from the rectangular walls of an apartment upward to the ceiling, and forming the horizontal part of the ceiling into a circle or ellipse.

Pentastyle. Having five columns in front.

Pent-roof. A roof with a slope on one side only.

Perch. A measure used in measuring stone work, being $24\frac{3}{4}$ cu ft and $16\frac{2}{3}$ cu ft, according to locality and custom.

Periptery. An edifice or temple surrounded by a peristyle.

Peristyle. A range of columns encircling an edifice, such as that which surrounds the cylindrical drum under the cupola of St. Paul's. The columns of a Greek peripteral temple form a peristyle also, the former being a circular, and the latter a quadrilateral peristyle.

Perpendicular Style. The third and last of the Pointed or Gothic style; also called the Florid style.

Persian Architecture. The architecture of the lands included in the modern kingdom of Persia, and those immediately adjoining which have received and retained Persian artistic influence. Architecturally, Persia may be considered under the following rules: (1) Darius, Xerxes, and their successors, 500 to 334 B.C. (2) Alexander and his successors, starting 334 B.C. (3) Parthian rule in the second and third centuries A.D. (4) Sassanians, A.D. 226 until the Moslem conquest. (5) The Moslem rule, resulting about the ninth century in an independent Mohammedan Kingdom. The later conquests, as of the Seljuks and by Genghis Khan do not alter the national character of the Persian Mohammedan art. The origin of the architecture of Persia must be sought for in that of the two countries conquered by her, viz., Babylon and Media. From the former she derived the raised platform, or terrace, on which her palaces were built, and the winged bulls. To the Medes she owed her porticoes and halls of columns. The precise position of Persian art in the history of the Mohammedan styles is debatable but some scholars consider it the fountain head. The varied buildings are treated with remarkable uniformity of style. The great mosques, medresseh, and caravanseries are built around large courts, usually square or rectangular, entered by an imposing vaulted portal and surrounded by arcades, usually in two stories, which give access to the various chambers, rooms, or cells behind them. As to details, it should be noted that neither the horseshoe nor the cusped arch prevails in Persia. The equilateral pointed arch occurs but rarely; the characteristic Persian arch resembles somewhat the Tudor arch of the Perpendicular. In the matter of ornament the Persians surpassed the western Moslems in ceramic decoration and in the flowing grace and freedom of their patterns as far as they were inferior to them in variety and splendor of ornament. It was Persian artists who carried the art of wall tiling into Turkey, Egypt, Sicily and Spain. The Persians are adepts in a certain kind of formal gardening, which adds to the effect of their palaces and squares and which was carried to India by Persian artists in the train of the Moguls in the sixteenth century.

Perspective Drawing. The art of making such a representation of an object upon a plane surface as shall present precisely the same appearance that the object itself would to the eye situated at a particular point.

Pews. A word of uncertain origin, signifying fixed seats in churches, composed of wood framing, mostly with ornamented ends. They seem to have come into general use early in the reign of Henry VI, and to have been rented and "well paid for" before the Reformation. Some bench ends are certainly of a decorated character, and some have been considered to be of the Early English period. They are sometimes of plain oak board, two and a half to three inches thick, chamfered, and with a necking and finial, generally called a poppy head; others are plainly paneled with bold cappings; in others the panels are ornamented with tracery or with the linen pattern, and sometimes with running foliages. The divisions are filled in with thin chamfered boarding, sometimes reaching to the floor, and sometimes only from the capping to the seat.

Picket. A narrow board, often pointed, used in making fences; a pale or paling.

Pier-glass. A mirror hanging between windows.

Piers. The solid parts of a wall between windows, and between voids generally. The term is also applied to masses of brickwork or masonry which are insulated to form supports to gates or to carry arches, posts, girders, etc.

Pilasters. Are flat square columns, attached to a wall, behind a column, or along the side of a building, and projecting from the wall about a fourth or a sixth part of their breadth. The Greeks had a slightly different design for the capitals of pilasters, and made them the same width at top as at bottom, but the Romans gave them the same capitals as the columns, and made them of diminished width at the top, similar to the columns.

Pile. A large stake or trunk of a tree, driven into soft ground, as at the bottom of a river, or in made land, for the support of a building.

Pillar, or Pyller. A word generally used to express the round or polygonal piers, or those surrounded with clustered columns, which carry the main arches of a building. Saxon and Early Norman pillars are generally stout cylindrical shafts built up of small stones. Sometimes, however, they are quite square, sometimes with other squares breaking out of them (this is more common in French and German work), sometimes with angular shafts, and sometimes they are plain octagons. In Romanesque Norman work the pillar is sometimes square, with two or more semicircular or half-columns attached. In the Early English period the pillars become loftier and lighter, and in most important buildings are a series of clustered columns, frequently of marble, placed side by side, sometimes set at intervals round a circular center, and sometimes almost touching each other. These shafts are often wholly detached from the central pillar, though grouped round it, in which case they are almost always of Purbeck or Bethersden marbles. In Decorated work the shafts on plan are very often placed round a square set anglewise, or a lozenge, the long way down the nave; the center or core itself is often worked into hollows or other moldings, to show between the shafts, and to form part of the composition. In this and the latter part of the previous style there is generally a fillet on the outer part of the shaft, forming what has been called a keel molding. They are also often, as it were, tied together by bands formed of rings of stone and sometimes of metal. The small pillars at the jambs of doors and windows, and in arcades, and also those slender columns attached to pillars, or standing detached, are generally called shafts.

Pin. A cylindrical piece of wood, iron, or steel, used to hold two or more pieces together, by passing through a hole in each of them, as in a mortise and tenon joint, or a pin joint of a truss.

PINNACLE

Pinnacle. An ornament originally forming the cap or crown of a buttress or small turret, but afterwards used on parapets at the corners of towers and in many other situations. It was a weight to counteract the thrust of the groining of roofs, particularly where there were flying buttresses; it stopped the tendency to slip of the stone copings of the gables, and counterpoised the thrust of spires; it formed the piers to steady the elegant perforated parapets of later periods; and in France, especially, served to counterbalance the weight of overhanging corbel tables, huge gargoyles, etc. In the Early English period the smaller buttresses

frequently finished with gablets, and the more important with pinnacles supported with clustered shafts. At this period the pinnacles were often supported on these shafts alone, and were open below; and in larger work in this and the subsequent periods they frequently form niches and contain statues. In France, pinnacles, like spires, seem to have been in use earlier than in England. There are small pinnacles at the angles of the tower in the Abbey of Saintes. At Roullet there are pinnacles in a similar position, each composed of four small shafts, with caps and bases surmounted with small pyramidal spires. In all these examples the towers have semicircular headed windows.

Pitch of a Roof. The proportion obtained by dividing the height by the span; thus, we speak of its being one-half, one-third, one-fourth. When the length of the rafters is equal to the breadth of the building it is denominated Gothic.

Pitching-piece. A horizontal timber, with one of its ends wedged into the wall at the top of a flight of stairs, to support the upper end of the rough strings.

Place. An open piece of ground surrounded by buildings, generally decorated with a statue, column, or other ornament.

Plan. A horizontal geometrical section of the walls of a building; or indications, on a horizontal plane, of the relative positions of the walls and partitions, with the various openings, such as windows and doors, recesses and projections, chimneys and chimney-breasts, columns, pilasters, etc. This term is often incorrectly used in the sense of Design.

Planceer. Is sometimes used in the same sense as soffit, but is more correctly applied to the soffit of the corona in a cornice.

Plastering. A mixture of lime, hair, and sand, to cover lath-work between timbers or rough walling, used from the earliest times, and very common in Roman work. In the Middle Ages, too, it was used not only in private, but in public constructions. On the inside face of old rubble walls it was not only used for purposes of cleanliness, rough work holding dirt and dust, but as a ground for distemper painting (tempera, or, as it is often improperly called, fresco), a species of ornaments often used in the Middle Ages. At St. Albans Abbey, England, the Norman work is plastered, and covered with lines imitating the joints of stone. The same thing is found in English Perpendicular work. On the outside of rubble walls, and often of wood framing, it was used as roughcast; when ornamented in patterns outside, it is called pargeting.

Plate. The piece of timber in a building which supports the end of the rafters.

Plinth. The square block at the base of a column or pedestal. In a wall, the term plinth is applied to the projecting base or water table, generally at the level of the first floor.

Plumb. Perpendicular; that is, standing according to a plumb line, as, the post of a house or wall is plumb.

Plumbing. The lead and iron pipes and other apparatus employed in conveying water, and for toilet purposes in a building; originally the art of casting and working in lead.

Ply. Used to denote the number of thicknesses of roofing paper, as three ply, four ply, etc.

Podium. A continued pedestal; a projection from a wall, forming a kind of gallery.

Polytriglyph. An intercolumniation in the Doric order of more than two triglyphs.

Poppy Heads. Probably from the French *poupée:* the finials or other ornaments which terminate the tops of bench ends, either to pews or stalls. They are sometimes small human heads, sometimes richly carved images, knots of foliage, or finials, and sometimes fleurs-de-lis simply cut out of the thickness of the bench end and chamfered.

POPPY HEAD

Porch. A covered erection forming a shelter to the entrance door of a large building. The earliest known are the long arcaded porches in front of the early Christian basilicas, called Narthex. In later times they assume two forms—one, the projecting erection covering the entrance at the west front of cathedrals, and divided into three or more doorways, etc ; and the other, a kind of covered chambers open at the ends, and having small windows at the sides as a protection from rain.

Portal. A name given to the deeply recessed and richly decorated entrance doors to the cathedrals in Continental Europe.

Portcullis. A strong framed grating of oak, the lower points shod with iron, and sometimes entirely made of metal, hung so as to slide up and down in grooves with counterbalances, and intended to protect the gateways of castles, etc.

Portico. An open space before the door or other entrance to any building, fronted with columns. A portico is distinguished as prostyle or *in antis* according as it projects from or recedes within the building, and is further designated by the number of columns its front may consist of.

Portugal, Architecture of. The architecture of the westernmost of all the states of Europe, now a republic. Although there are a few buildings here which date from the tenth century, it is almost impossible to trace through them any continuous architectural development, for the numerous earthquakes and hostile invasions have made havoc. There is a decorative feature of Portuguese architecture which deserves mention, namely, the extensive use of wall tiling.

Post. Square timber set on end. The term is especially applied to those which support the corners of a building, and are framed into bressummers or crossbeams under the walls.

Posticum. A portico behind a temple.

Presbytery. A work applied to various parts of large churches in a very ambiguous way. Some consider it to be the choir itself; others, what is now named the sacrarium. Traditionally, however, it seems to be applied to the vacant space between the back of the high altar and the entrance to the lady-chapel, as at Lincoln and Chichester; in other words, the back- or retro-choir.

Priming. The laying on of the first shade of color, in oil paint, and generally consisting mostly of oil, to protect and fill the wood.

Priory. A monastic establishment, generally in connection with an abbey, and presided over by a prior, who was a subordinate to the abbot, and held much the same relation to that dignitary as a dean does to a bishop.

Profile. The outline; the contour of a part, or the parts composing an order, as of a base, cornice, etc.; also, the perpendicular section. It is in the just proportion of their profiles that the chief beauties of the different orders

of architecture depend. The ancients were most careful of the profiles of their moldings.

Projet. (Fr.) Finished presentation of a design problem.

Proscenium. The front part of the stage of ancient theaters, on which the actors performed.

Prostyle. A portico in which the columns project from the building of which it is attached.

Protractor. A mathematical instrument for laying down and measuring angles on paper, used in drawings or plotting.

Pseudo-classic Architecture. That phase of neoclassic architecture which marked the most stilted period of post Renaissance art, when, under the influence of Vitruvius' writings, and those of his modern disciples, the most formal imitation of Roman architecture prevailed, and it was the aim to revive the whole art of Rome.

Pseudo-dipteral. False double-winged. When the inner row of columns of a dipteral arrangement is omitted and the space from the wall of the building to the columns is preserved, it is pseudo-dipteral.

Puddle. To settle loose dirt by turning on water, so as to render it firm and solid.

Pugging. A coarse kind of mortar laid on the boarding, between floor joists, to prevent the passage of sound; also called deafening.

Pulpit. A raised platform with enclosed front, whence sermons, homilies, etc., were delivered. Pulpits were probably derived in their modern form from the ambones in the early Christian church. There are many old pulpits of stone, though the majority are of wood. Those in the churches are generally hexagonal or octagonal; and some stand on stone bases, and others on slender wooden stems, like columns. The designs vary according to the periods in which they were erected, having paneling, tracery, cuspings, crockets, and other ornaments then in use. Some are extremely rich, and ornamented with color and gilding. A few also have fine canopies or sounding boards. Their usual place is in the nave, mostly on the north side, against the second pier from the chancel arch. Pulpits for addressing the people in the open air were common in the Mediæval period, and stood near a road or cross. Thus, there was one at Spitalfields, and one at St. Paul's, London. External pulpits still remain at Magdalen College, Oxford, and at Shrewsbury, England.

Purlins. Those pieces of timbers which support the rafters to prevent them from sinking.

Putlog. Horizontal pieces for supporting the floor of a scaffold, one end being inserted into putlog holes, left for that purpose in the masonry.

Putty in Plastering. Lump lime slacked with water to the consistency of cream, and then left to harden by evaporation till it becomes like soft putty. It is then mixed with plaster of Paris, or sand, for the finishing coat.

Puzzolana. A grayish earth used for building under water.

Pyramid. A solid, having one of its sides, called a base, a plane figure, and the other sides triangles, these points joining in one point at the top, called the vertex. Pyramids are called triangular, square, etc., according to the form of their bases.

Pyx. In Roman Catholic churches, the box in which the host, or consecrated wafer, is kept.

Quadrangle. A square or quadrangular court surrounded by buildings, as was often done formerly in monasteries, colleges, etc.

Quarry. A pane of glass cut in a diamond or lozenge form.

Quarry-face. Ashlar as it comes from the quarry, squared off for the joints only, with split face. In distinction from Rock-face, in that the latter may be weather-worn, while Quarry-face should be fresh split. The terms are often used indiscriminately.

Quatrefoil. Any small panel or perforation in the form of a four-leaved flower. Sometimes used alone, sometimes in circles and over the aisle windows, but more frequently in square panels. They are generally cusped, and the cusps are often feathered.

Queen Truss. A truss framed with two vertical tie-posts, in distinction from the king-post, which has but one. The upright ties are called Queen-posts.

Quirk Moldings. The convex part of Grecian moldings when they recede at the top, forming a reëntrant angle, with the surface which covers the moldings.

Quoins. Large squared stones at the angles of buildings, buttresses, etc., generally used to stop the rubble or rough stone work, and that the angles may be true and stronger. Saxon quoin stones are said to have been composed of one long and one short stone alternately. Early quoins are generally roughly axed; in later times they had a draught tooled by the chisel round the outside edges, and later still were worked fine from the saw.

Rabbet. A continuous small recess, generally understood as having a right-angle included between its sides, especially one whose sides enclose a relatively restricted area; one formed by two planes, very narrow as compared with their length, such as the small recess on a door-frame, into which the edge of a door is made to fit, the recess of a brick jamb to receive a window-frame, and the like.

Rafters. The joist to which the roof-boarding is nailed. *Principal rafters* are the upper timbers in a truss, having the same inclination as the common rafters.

Rail. A piece of timber or metal extending from one post to another, as in fences, balustrades, staircases, etc. In framing and paneling, the horizontal pieces are called rails, and the perpendicular, *stiles*.

Raking. Moldings whose arrises are inclined to the horizon.

Ramp. A concavity on the upper side of hand railings formed over risers, made by a sudden rise of the steps above. Any concave bend or slope in the cap or upper member of any piece of ascending or descending workmanship.

Rampant. A term applied to an arch whose abutments spring from an inclined plane.

Random Work. A term used by stone-masons for stones fitted together at random without any attempt at laying them in courses. *Random Coursed Work* is a like term applied to work coursed in horizontal beds, but the stones are of any height, and fitted to one another.

Range Work. Ashlar laid in horizontal courses; same as coursed ashlar.

Rebate. A groove on the edges of a board.

Recess. A depth of some inches in the thickness of a wall, as a niche, etc.

Refectory. The hall of a monastery, convent, etc., where the religious took their chief meals together. It much resembled the great halls of mansions, castles, etc., except that there frequently was a sort of ambo, approached by steps, from which to read the Legenda Sanctorum, etc., during meals.

Reglet. A flat, narrow molding, used to separate from each other the parts of members of compartments and panels, to form frets, knots, etc.

Renaissance (a new birth). A name given to the revival of Roman architecture which sprang into existence in Italy as early as the beginning of the fifteenth century, and reached its zenith in that country at the close of the century. There are several divisions of this style as developed in different localities; viz.

The Florentine Renaissance, of which the Pitti Place, by Brunelleschi, is one of the best examples.

The Venetian Renaissance, characterized by its elegance and richness.

The Roman Renaissance, which originated in Rome, under the architects known as Bronte, Vignola, and Michael Angelo. Of this style the Farnese Palace, St. Peter's, and the modern Capitol at Rome are the best examples.

The French Renaissance, introduced into France in the latter part of the fifteenth century, by Italian architects, where it flourished until the middle of the seventeenth century. The Renaissance style was introduced into Germany about the middle of the sixteenth century, and into England about the same time by John of Padua, architect to Henry VIII. This style in England is generally known under the name of Elizabethan.

Rendering. In drawing, finishing a perspective drawing in ink or color, to bring out the spirit and effect of the design. The first coat of plaster on brick or stone work.

Rendu. (Fr.) Delivery of the projet.

Reredos, Dorsal, or **Dossel.** The screen or other ornamental work at the back of an altar. In some large English cathedrals, as Winchester, Durham, St. Albans, etc., this is a mass of splendid tabernacle work, reaching nearly to the groining. In smaller churches there are sometimes ranges of arcades or panelings behind the altars; but, in general, the walls at the back and sides of them were of plain masonry, and adorned with hangings or paraments. In the large churches of Continental Europe the high altar usually stands under a sort of canopy or ciborium, and the sacrarium is hung round at the back and sides with curtains on movable rods.

Reticulated Work. That in which the courses are arranged in a form like the meshes of a net. The stones or bricks are square and placed lozenge-wise.

Return. The continuation of a molding, projection, etc., in an opposite direction.

Return Head. One that appears both on the face and edge of a work.

Reveal. The two vertical sides of an aperture, between the front of a wall and the window or door-frame.

Rib. A molding or projecting piece upon the interior of a vault, or used to form tracery and the like. The earliest groining had no ribs. In early Norman times plain flat arches crossed each other, forming ogive ribs. These by degrees became narrower, had greater projection, and were chamfered. In later Norman work the ribs were often formed of a large roll placed upon the flat band, and then of two rolls side by side with a smaller roll or a fillet between them, much like the lower member. Sometimes they are enriched with zigzags and other Norman decorations, and about this time bosses

became of very general use. As styles progressed the moldings were more undercut, richer, and more elaborate, and had the dog-tooth or ball-flower or other characteristic ornament in the hollows. In all instances the moldings are of similar contours to those of arches, etc., of the respective periods. Later, wooden roofs are often formed into cants or polygonal barred vaults, and in these the ribs are generally a cluster of rounds, and form square or stellar panels, with carved bosses or shields at the intersections.

Ridge. The top of a roof which rises to an acute angle.

Ridge-pole. The highest horizontal timber in a roof, extending from top to top of the several pairs of rafters of the trusses, for supporting the heads of the jack rafters.

Relievo, or Relief. The projection of an architectural ornament.

Rise. The distance through which anything rises, as the rise of a stair, or inclined plane.

Riser. The vertical board under the tread in stairs.

Rococo Style. A name given to that variety of the Renaissance which was in vogue during the seventeenth and the latter part of the sixteenth century.

Roman Imperial Architecture. The architecture of the Roman dominion in Europe, Asia, and Africa, ending with the fourth century A.D. With the exception of fragments of walls and of a few simple buildings, Roman architecture is represented by those monuments which were erected during the Empire, and as the style was first developed in Rome and then spread throughout the various countries subjugated, with such modifications as the materials of the country and the labor to be obtained required and as the climate suggested, the term " Roman Imperial Architecture " has been adopted to prevent confusion. Etruscan architecture is the first source of what may be called its elements and in one sense the most important. It was mainly through her paved roads that Rome was able to bring into connection all the chief cities of the Empire, by the solid construction of her walls to render the cities she founded secure against attack, and by employment of arched construction to roof over her buildings with an imperishable material, to build bridges and aqueducts (the latter of vital importance in all her Eastern possessions), and lastly to drain off water from marshy districts. The second source was Greek architecture. The orders, Doric, Ionic and Corinthian, where employed in the temple, the basilica and thermæ, underwent but little change; the great scientific advance, however, made in the quarrying of stone and marble and in the transport of large masses of stone, enabled the Roman architect to substitute the monolith for the Greek column built in several courses, and the greater display of richness in the Corinthian order led to its almost universal adoption. There is one other order introduced by the Romans, the Composite, which is a mixture of two orders. The earliest example of the super-imposition of orders is found in Rome. The notable feature of Imperial Roman architecture, when compared with the history of more ancient styles, is the immense variety of buildings of every type. By far the greatest development in Roman Imperial architecture is that which in the thermæ and palaces, is found in the employment of the barrel vaults, the intersecting barrel vault, and the dome. These features led to erection of buildings entirely homogeneous in the material employed, and of so lasting and durable a nature that, but for earthquakes and the destructive action of mankind, they might all have remained perfect to the present day. The other structures which were developed were the arched entrances to towns, tri-

umphal arches, tombs, viaducts and colonnaded streets. In some instances a knowledge of a type of iron construction is shown.

Romanesque Style. The term Romanesque embraces all those styles of architecture which prevailed between the destruction of the Roman Empire and the beginning of Gothic architecture. In it are included the Early Roman Christian architecture, Byzantine, Mahometan, and the later Romanesque architecture proper, which was developed in Italy, France, England, and Germany. This later Romanesque, which was quite different from the preceding, came into vogue during the tenth century, and reached its height during the twelfth century, and in the thirteenth century gave way to the Pointed or Gothic style. In England, Romanesque architecture is known under the name of the Saxon, Norman, and Lombard styles, according to the different political periods.

Rood. A name applied to a crucifix, particularly to those which were placed in the rood-loft or chancel screens. These generally had not only the image of the crucified Saviour, but also those of St. John and the Virgin Mary standing one on each side. Sometimes other saints and angels are by them, and the top of the screen is set with candlesticks or other decoration.

Rood-loft, Rood-screen, Rood-beam, Jube Gallery, etc. The arrangement to carry the crucifix or rood, and to screen off the chancel from the rest of the church during the breviary services, and as a place whence to read certain parts of those services. Sometimes the crucifix is carried simply on a strong transverse beam, with or without a low screen, with folding-doors below but forming no part of such support. In European churches the general construction of wooden screens is close paneling beneath, about 3 feet to 3 feet 6 inches high, on which stands screen work composed of slender turned balusters or regular wooden mullions, supporting tracery more or less rich, with cornices, cresting, etc., and often painted in brilliant colors and gilded. These not only enclose the chancels, but also chapels, chantries, and sometimes even tombs. In English mansions, and some private houses, the great halls were screened off by a low passage at the end opposite to the dais, over which was a gallery for the use of minstrels or spectators. These screens were sometimes close and sometimes glazed.

Rood-tower. A name given by some writers to the central tower, or that over the intersection of the nave and chancel with the transepts.

Roof. The covering or upper part of any building.

Roofing. The material put on a roof to make it water-tight.

Rose Window. A name given to a circular window with radiating tracery; called also wheel window.

Rostrum. An elevated platform from which a speaker addresses an audience.

Rotunda. A building which is round both within and without. A circular room under a dome in large buildings is also called the rotunda.

Roughcast. A sort of external plastering in which small sharp stones are mixed, and which, when wet, is forcibly thrown or cast from a trowel against the wall, to which it forms a coating of pleasing appearance. Roughcast work has been used in Europe for several centuries, where it was much used in timber houses, and when well executed the work is sound and durable. The mortar for roughcast work should always have cement mixed with it.

Rubble Work. Masonry of rough, undressed stones. When only the roughest irregularities are knocked off, it is called scabbled rubble, and when

the stones in each course are rudely dressed to nearly a uniform height, ranged rubble.

Rudenture. The figure of a rope or staff, which is frequently used to fill up the flutings of columns, the convexity of which contrasts with the concavity of the flutings, and serves to strengthen the edges. Sometimes, instead of a convex shape, the flutings are filled with a flat surface; sometimes they are ornamentally carved, and sometimes on pilasters, etc. Rudentures are used in relief without flutings, as their use is to give greater solidity to the lower part of the shaft, and secure the edges. They are generally only used in columns which rise from the ground and are not to reach above one-third of the height of the shaft.

Russia, Architecture of. The architecture of as much of that country as lies west of the Ural Mountains. In this vast region there are many remains of ancient building showing great capacity for art of a semibarbaric sort, and much of that picturesqueness which comes from massive building of unusual height and expressive outline, as in fortification. The Byzantine influence entered not earlier than the twelfth century and came partly from the monasteries of the Greek church in the south and partly from Constantinople direct. The simple log buildings of the peasantry, including churches as well as large and small residences and village houses, are extremely attractive. Beginning with the reign of Peter the Great, buildings of modern European form have been imitated in Russia, and palaces for the sovereign and for the nobles have followed the neoclassic style of the epoch, but generally without fortunate result. The taste is often barbarous without being effective, the exteriors pompous without being stately.

Rustic or Rock Work. A mode of building in imitation of nature. This term is applied to those courses of stone work the face of which is jagged or picked so as to present a rough surface. That work is also called rustic in which the horizontal and vertical channels are cut in the joinings of stones, so that when placed together an angular channel is formed at each joint. *Frosted rustic work* has the margins of the stones reduced to a plane parallel to the plane of the wall, the intermediate parts having an irregular surface. *Vermiculated rustic work* has these intermediate parts so worked as to have the appearance of having been eaten by worms. *Rustic chamfered work,* in which the face of the stones is smooth, and parallel to the face of the wall, and the angles beveled to an angle of one hundred and thirty-five degrees with the face so that two stones coming together on the wall, the beveling will form an internal right angle.

Sacristy. A small chamber attached to churches, where the chalices, vestments, books, etc., were kept by the officer called the sacristan. In the early Christian basilicas there were two semicircular recesses or apsides, one on each side of the altar. One of these served as a sacristy, and the other as the bibliotheca or library. Some have supposed the sacristy to have been the place where the vestments were kept, and the vestry that where the priests put them on; but we find from Durandus that the sacrarium was used for both these purposes. Sometimes the place where the altar stands enclosed by the rails has been called sacrarium.

Saddle Bars. Narrow horizontal iron bars passing from mullion to mullion, and often through the whole window, from side to side, to steady the stone work, and to form stays, to which the lead work is secured. When the bays of the windows are wide, the lead lights are further strengthened by upright bars passing through eyes forged on the saddle bars, and called stanchions.

When saddle bars pass right through the mullions in one piece, and are secured to the jambs, they have sometimes been called stay bars.

Sagging. The bending of a body in the middle by its own weight, or the load upon it.

Salient. A projection.

Salon. A spacious and elegant apartment for the reception of company, or for state purposes, or for the reception of paintings, and usually extending through two stories of the house. It may be square, oblong, polygonal, or circular.

Sanctuary. That part of a church where the altar is placed; also, the most sacred or retired part of a temple. A place for divine worship; a church.

Sanctus Bell-cot, or Turret. A turret or enclosure to hold the small bell sounded at various parts of the service, particularly where the words "Sanctus," etc., are read. This differs but little from the common bell-cot, except that it is generally on the top of the arch dividing the nave from the chancel. Sometimes, however, the bell seems to have been placed in a cot outside the wall. In England sanctus bells have also been placed over the gables of porches. In Continental Europe they run up into a sort of small slender spire, called *flèche* in France, and *guglio* in Italy.

Saracenic Architecture. That Eastern style employed by the Saracens, and which distributed itself over the world with the religion of Mahomet. It is a modification and combination of the various styles of the countries which they conquered.

Sarcophagus. A tomb or coffin made of stone, and intended to contain the body.

Sash. The framework which holds the glass in a window.

Scabble. To dress off the rougher projections of stones for rubble masonry with a stone axe or scabbling hammer.

Scagliola. An imitation of colored marbles in plaster work, made by a combination of gypsum, glue, isinglass, and coloring matter, and finished with a high polish, invented between 1600 and 1649.

Scandinavia, Architecture of. The architecture of the great peninsula now occupied by the two kingdoms of Sweden and Norway. The Scandinavian lands are sometimes held to include Denmark which is here treated separately. Norway contains some ancient timber churches, construction of which is not unlike those in New England in the seventeenth and eighteenth centuries. Romanesque stone vaulted churches are not unknown. The neoclassic architecture of Scandinavia is largely a matter of the residences of the nobility. Some of these residences are of extraordinary interest, containing a character of bold pseudo-Renaissance design reminding one of good seventeenth century German work, but of still greater independence and daring in the treatment of the semiclassical details. The late seventeenth century and the early eighteenth century have left civic buildings of grave and sedate aspect.

Scantling. The dimensions of a piece of timber in breadth and thickness; also, studding for a partition, when under five inches square.

Scarfing. The joining and bolting of two pieces of timber together transversely, so that the two appear as one.

Sconce. A fixed hanging or projecting candlestick.

Scotia. A concave molding, most commonly used in bases, which projects a deep shadow on itself, and is thereby a most effective molding under the eye,

as in a base. It is like a reversed ovolo, or, rather, what the mold of an avolo would present.

Scratch Coat. The first coat of plaster, which is scratched to afford a bond for the second coat.

Screeds. Long narrow strips of plaster put on horizontally along a wall, and carefully faced out of wind, to serve as guides for plastering the wide intervals between them.

Screen. Any construction subdividing one part of a building from another, as a choir, chantry, chapel, etc. The earliest screens are the low marble podia shutting off the chorus cantantium in the Roman basilicas, and the perforated cancelli enclosing the bema, altar, and seats of the bishops and presbyters. The chief screens in a church are those which enclose the choir or the place where the breviary services are recited. In Continental Europe this is done not only by doors and screen work, but also, when these are of open work, by curtains, the laity having no part in these services. In England screens were of two kinds: one, of open wood-work, generally called rood-screens or jubes, and which the French call *grilles, clôtures du chœur,* the other, massive enclosures of stone work enriched with niches, tabernacles, canopies, pinnacles, statues, crestings, etc., as at Canterbury, York, Gloucester, and many other places.

Scribing. Fitting wood-work to an irregular surface

Scupper. Outlets for overflow of water in outside or court walls, to drain floor of water from automatic sprinklers or fire-hose in case of fire.

Section. A drawing showing the internal heights of the various parts of a building. It supposes the building to be cut through entirely, so as to exhibit the walls, the heights of the internal doors and other apertures, the heights of the stories, thicknesses of the floors, etc. It is one of the species of drawings necessary to the exhibition of a Design.

Sedilia. Seats used by the celebrants during the pauses in the mass. They are generally three in number—for the priest, deacon, and sub-deacon—and are in England almost always a species of niches cut into the south walls of churches, separated by shafts or by a species of mullions, and crowned with canopies, pinnacles, and other enrichments more or less elaborate. The piscina and ambry sometimes are attached to them. In Continental Europe the sedilia are often movable seats; a single stone seat has rarely been found.

Setback. A flat, plain set-off in a wall; also, a setting back of the outside wall of a building for some distance from the street-line, especially, in tall buildings, such a setting back at a particular height in the building, or one of a number of such settings back at different heights, for the purpose of allowing better light and ventilation in the street.

Set-off. The horizontal line shown where a wall is reduced in thickness, and, consequently, the part of the thicker portion appears projecting before the thinner. In plinths this is generally simply chamfered. In other parts of work the set-off is generally concealed by a projecting string. Where, as in parapets, the upper part projects before the lower, the break is generally hid by a corbel table. The portions of buttress caps which recede one behind another are also called set-offs.

Shaft. In Classical architecture that part of a column between the necking and the apophyge at the top of the base. In later times the term is applied to slender columns either standing alone or in connection with pillars, buttresses, jambs, vaulting, etc.

Shed Roof, or Lean-to. A roof with only one set of rafters, falling from a higher to a lower wall, like an aisle roof.

Shore. A piece of timber placed in an oblique direction to support a building or wall temporarily while it is being repaired or altered.

Shrine. A sort of ark or chest to hold relics. It is sometimes merely a small box, generally with a raised top like a roof; sometimes an actual model of churches; sometimes a large construction, like that of Edward the Confessor at Westminster, of St. Genevieve at Paris, etc. Many are covered with jewels in the richest way; that of San Carlo Borromeo, at Milan, is of beaten silver.

Sills. Are the timbers on the ground which support the posts and superstructure of a timber building. The term is most frequently applied to those pieces of timber or stone at the bottom of doors or windows.

Skewback. The inclined stone from which an arch springs.

Skintled Brickwork. Irregularly formed brickwork arranged with variations in projections on the exterior face-wall, usually formed of bricks of irregular shape.

Skirtings. The narrow boards which form a plinth around the margin of a floor, now generally called the base.

Sleeper. A piece of timber laid on the ground to receive floor joists.

Soffit. The lower horizontal face of anything as, for example, of an entablature resting on and lying open between the columns, or the under face of an arch where its thickness is seen.

Sound Board. The covering of a pulpit to deflect the sound into a church.

South America, Architecture of. *Ancient:* The most interesting development occurred previous to the conquest of Peru by the Spaniards in 1532. The extent and time of its beginning are not known. At the time of the Spanish invasion, the entire territory west of the Andes was in possession of the Inca dynasty. Inca architecture is characterized by distinctly stone construction. There is no suggestion of wooden types as in Greece and Egypt. The ruins are of large palaces or public buildings. The palaces and temples are built around courts. *Modern:* The most interesting monuments of modern architecture are situated in Peru. The architecture of Brazil is quite recent, built mainly of brick, the splendid woods of the country being used in the interior. Like the cities of Brazil, those of Venezuela, Colombia, Chile, the Argentine Republic, and other South American countries are quite modern.

Spall. Bad or broken brick; stone chips.

Spain, Architecture of. The Iberians, or pre-Roman inhabitants of Spain, left no surviving monuments beyond a few slightly known structures in the northern Basque provinces. Only fragmentary examples of Roman aqueducts, temples and theaters remain. A few scattered remains of seventh and eighth century mediæval buildings present a curious analogy, in style, plan, and arrangement, to some of the Roman or Early Christian work of Syria. The Moorish invasion amalgamated rival interests into the mediæval kingdom of Spain and introduced the Renaissance. In the south, the Moors found little to preserve when they first entered the kingdom, and their own architectural work strongly impressed the Christian conquerors, so that as the Moslems were driven out and the Christian influence gained the ascendancy, the Moorish work was, on the whole, little disturbed, resulting in our finding it in its present condition today, with but a slight admixture of the Renaissance. The existing architectural remains present, in their geographical distribution, a curious analogy to the conditions of the soil and climate, the Gothic and

Romanesque being chiefly found in the north, the Moorish in the south, and the neoclassic along the central plateau. There does not appear to be in Spain a well-defined development or consecutive growth from the mediæval to the modern styles. Rather, each style appears broadly and frankly borrowed outright, the only essentially Spanish factors being displayed in a few peculiarities of plan and in the spirit of the detail, the noticeable lack being in inventive progression rather than in ability to adapt.

Span. The distance between the supports of a beam, girder, arch, truss, etc.

Spandrel, or Spandril. The space between any arch or curved brace and the level label, beams, etc., over the same. The spandrels over doorways in Perpendicular works are generally richly decorated. Also, an exterior non-bearing wall in skeleton construction built between columns or piers and wholly supported at each story.

Specification. *Architect's.* The designation of the kind, quality, and quantity of work and material to go in a building, in conjunction with the working drawings.

Spire. A sharply pointed pyramid or large pinnacle, generally octagonal in England, and forming a finish to the stops of towers. Timber spires are very common in England. Some are covered with lead in flat sheets, others with the same metal in narrow strips laid diagonally. Very many are covered with shingles. In Continental Europe there are some elegant examples of spires of open timber work covered with lead.

Splayed. The jamb of a door, or anything else of which one side makes an oblique angle with the other.

Springer. The stone from which an arch springs; in some cases this is a capital, or impost; in other cases the moldings continue down the pier. The lowest stone of the gable is sometimes called a springer.

Squinches. Small arches or corbled set-offs running diagonally and, as it were, cutting off the corners of the interior of towers, to bring them from the square to the octagon, etc., to carry the spire.

Squint. An oblique opening in the wall of a church; especially, in mediæval architecture, an opening so placed as to afford a view of the high altar from the transept or aisles.

Staging. A structure of posts and boards for supporting workmen and material in buildings.

Stall. A fixed seat in the choir for the use of the clergy. In early Christian times the thronus cathedra, or seat of the bishop, was in the center of the apsis or bema behind the altar, and against the wall; those of the presbyters also were against the wall, branching off from side to side around the semicircle. In later times the stalls occupied both sides of the choir, return seats being placed at the ends for the prior, dean, precentor, chancellor, or other officers. In general, in cathedrals, each stall is surmounted by tabernacle work, and rich canopies, generally of oak.

Stanchion. A word derived from the French *étançon*, a wooden post, applied to the upright iron bars which pass through the eyes of the saddle bars or horizontal irons to steady the lead lights. The French call the latter *traverses*, the stanchions *montants*, and the whole arrangement *armature*. Stanchions frequently finish with ornamental heads forged out of the iron.

Steeple. A general name for the whole arrangement of tower, belfry, spire, etc.

Stereobate. A basement, distinguished from the nearly equivalent term stylobate by the absence of columns.

Stile. The upright piece in framing or paneling.

Stilted. Anything raised above its usual level. An arch is stilted when its center is raised above the line from which the arch appears to spring.

Stoa. A portico used by the ancient Greeks as a shady promenade or meeting place, where conversation might be held or speakers heard. The stoa took the form of a roof structure, the length of which was great as compared to its depth. Ordinarily, there was at the back an enclosing wall, and in front, facing the street or public square, a colonnade. The floor was generally raised a few steps above the street. Some were two stories in height.

Stoop. A seat before the door; often a porch with a balustrade and seats on the sides.

Stoup. A basin for holy water at the entrance of Roman Catholic churches, into which all who enter dip their fingers and cross themselves.

Straight Arch. A form of arch in which the intrados is straight, but with its joints radiating as in a common arch.

Strap. An iron plate for connecting two or more timbers, to which it is screwed by bolts. It generally passes around one of the timbers.

Stretcher. A brick or block of masonry laid lengthwise of a wall.

String Board. A board placed next to the well-hole in wooden stairs, terminating the ends of the steps. The string piece is the piece of board put under the treads and risers for a support, and forming the support of the stair.

String-course. A narrow, vertically faced and slightly projecting course in an elevation. If window-sills are made continuous, they form a string-course; but if this course is made thicker or deeper than ordinary window-sills, or covers a set-off in the wall, it becomes a blocking-course. Also, horizontal moldings running under windows, separating the walls from the plain part of the parapets, dividing towers into stories or stages, etc. Their section is much the same as the labels of the respective periods; in fact, these last, after passing round the windows, frequently run on horizontally and form strings. Like labels, they are often decorated with foliages, ball-flowers, etc.

Stucco. Any material used as a covering for walls and the like, put on wet and drying hard and durable. Plaster where applied to walls in the usual way is a kind of stucco, and the hard finish is almost exactly like fine Roman stucco except that it is applied in only one thin coat instead of many. Vitruvius speaks of three coats mixed with sand and three coats mixed with marble dust, but does not give the thickness of coats, nor, what would answer the same purpose, how wet the mixture was made. He speaks of well-finished stucco shining so as to reflect the images falling upon it, and states that persons used to get slabs of plaster from ancient walls and use them for tables, the material being so beautiful in itself. The term is generally applied to out-of-door work. Even in modern fireproof buildings the decorative use of fine plastering to replace woodwork, as for dados and the like, is not in the United States called stucco, but takes the name of the material used, generally a proprietary name. The term is used commonly for outer walls. The practical value of stucco is very great as being so nearly impervious to water; thus an excellent wall three stories high, or even higher, may be built with eight inches of brick on the inner side, four inches of brick on the outer side, an air space of two or four inches across which the outer and the inner walls are well tied,

and two coats of well-mixed and well-laid stucco on the exterior, this being finally painted with oil paint.

Studs, or Studding. The small timbers used in partitions and outside wooden walls, to which the laths and boards are nailed.

Style. The term style in architecture has obtained a conventional meaning beyond its simpler one, which applies only to columns and columnar arrangements. It is now used to signify the differences in the moldings, general outlines, ornaments, and other details which exist between the works of various nations, and also those differences which are found to exist between the works of any nation at different times.

Stylobate. A basement to columns. Stylobate is synonymous with pedestal, but is applied to a continued and unbroken substructure or basement to columns, while the latter term is confined to insulated supports. The Greek temples generally had three or more steps all around the temple, the base of the column resting on the top step; this was the stylobate.

Subsellium. A name sometimes given to the seat in the stalls of churches; same as miserere.

Summer. A girder or main-beam of a floor; if supported on two-story posts and open below, it is called a Brace-summer.

Sump. A swamp, bog, or muddy pool (now provincial English); also, a pit, well, or the like, in which water or other liquid is collected; in mining, a space at the bottom of a shaft where water is allowed to collect; in mechanics, a reservoir for oil situated at the lowest point in a circulating system for lubricating-oil in an internal-combustion engine.

Surbase. A cornice or series of moldings on the top of the base of a pedestal-podium, etc.; a molding above the base.

Surface. To make plane and smooth.

Syria, Architecture of. The architecture of the country stretching from the eastern coast of the Mediterranean eastward to the Euphrates scarcely possesses an indigenous architectural style, as the Semitic tribes who peopled this region were not a building race. In all the earlier work of the country, down to the Mohammedan invasion in the seventh century, there are two special characteristics not found elsewhere: (1) Monolithism, employment of immense blocks of masonry, essentially Phœnician. (2) Drafted masonry; in order to obtain a fine and accurate joint, the masons worked a draft round the edge of each stone, thus constituting what is known as rusticated masonry. The architecture may be grouped under the following divisions: Herodian and Roman work, synagogues, Roman work of second century and later, colonnaded streets, Roman temples, Roman tombs, theaters, Sassanian or doubtful buildings, Christian buildings, Syrian round-arched style, Crusaders' work, Moslem work.

Systyle. An intercolumniation to which two diameters are assigned.

Tabernacle. A species of niche or recess in which an image may be placed. They are generally highly ornamented and often surmounted with crocketed gables. The word tabernacle is also often used to denote the receptacle for relics, which was often made in the form of a small house or church.

Tabernacle Work. The rich ornamental tracery forming the canopy, etc., to a tabernacle, is called tabernacle work; it is common in the stalls and screens of cathedrals, and in them is generally open or pierced through.

Tail Trimmer. A trimmer next to the wall, into which the ends of joists are fastened to avoid flues.

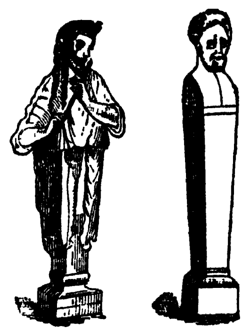
Tamp. To pound the earth down around a wall after it has been thrown in.

Tapestry. A kind of woven hangings of wool or silk, ornamented with figures, and used formerly to cover and adorn the walls of rooms. They were often of the most costly materials and beautifully embroidered.

Temple. An edifice destined, in the earliest times, for the public exercise of religious worship.

Templet, or **Template.** A mold used by masons for cutting or setting work. A short piece of timber sometimes laid under a girder

Terminal. Figures of which the upper parts only, or perhaps the head and shoulders alone, are carved, the rest running into a parallelopiped, and sometimes into a diminishing pedestal, with feet indicated below, or even without them, are called terminal figures.



ANCIENT TERMINI

Terra-cotta. Baked clay of a fine quality. Much used for bas-reliefs for adorning the friezes of temples. In modern times employed for architectural ornaments, statues, vases, etc.

Terrazzo. A concrete pavement used for floors in the province of Venetia, even in houses of some pretensions to elegance. Lime-mortar made unusually dry is the principal material; in this are inlaid small pieces of marble, usually not too large to pass through a ring an inch and a half in diameter. The whole is beaten hard, rubbed down, and polished.

Tessellated Pavements. Those formed of tesseræ, or, as some write it, tessellæ, or small cubes from half an inch to an inch square, like dice, of pottery, stone, marble, enamel, etc.

Tetrastyle. A portico of four columns in front.

Tholobate. That on which a dome or cupola rests. This is a term not in general use, but it is not the less of useful application. What is generally termed the attic above the peristyle and under the cupola of St. Paul's, London, would be correctly designated the tholobate. A tholobate of a different description, and one to which no other name can well be applied, is the circular substructure to the cupola of the University College, London.

Throat. A channel or groove made on the under-side of a string-course, coping, etc., to prevent water from running inward toward the walls.

Tie. A timber, rod, chain, etc., binding two bodies together, which have a tendency to separate or diverge from each other. The *tie-beam* connects the bottom of a pair of principal rafters, and prevents them from bursting out the wall.

Tiles. Flat pieces of clay burned in kilns, to cover roofs in place of slates or lead. Also, flat pieces of burned clay, either plain or ornamented, glazed or unglazed, used for floors, wainscoting, and about fireplaces, etc. Small square pieces of marble are also called tile.

Tongue. The part of a board left projecting, to be inserted into a groove.

Tooth Ornament. One of the peculiar marks of the Early English period of Gothic architecture, generally inserted in the hollow moldings of doorways, windows, etc.

Torso. A multilated statue of which nothing remains but the trunk. Columns with twisted shafts have also this term. Of this kind there are several varieties.

Torus. A protuberance or swelling, a molding whose form is convex, and generally nearly approaches a semicircle. It is most frequently used in bases, and is generally the lowest molding in a base.

TORUS

Tower. An elevated building originally designed for purposes of defence. Those buildings are of the remotest antiquity, and are, indeed, mentioned in the earliest Scriptures. In mediæval times they were generally attached to churches, to cemeteries, to castles, or used as bell-towers in public places of large cities. In churches, the towers of the Saxon period were generally square. Norman towers were also generally square. Many were entirely without buttresses; others had broad, flat, shallow projections which served for this purpose. The lower windows were very narrow, with extremely wide splays inside, probably intended to be defended by archers. The upper windows, like those of the preceding style, were generally separated into two lights, but by a shaft or short column, and not by a baluster. Early English towers were generally taller, and of more elegant proportions. They almost always had large projecting buttresses, and frequently stone staircases. The lower windows, as in the former style, were frequently mere arrow-slits; the upper were in couplets or triplets, and sometimes the tower top had an arcade all around. The spires were generally broach spires; but sometimes the tower tops finished with corbel courses and plain parapets, and (rarely) with pinnacles. There are a few Early English towers which break into the octagon from the square toward the top, and still fewer which finish with two gables. Both these methods of termination, however, are common in Continental Europe. At Vendôme, Chartres, and Senlis the towers have octagonal upper stages surrounded with pinnacles, from which elegant spires arise. In the North of Italy, and in Rome, they are generally tall square shafts in four to six stages, without buttresses, with couplets or triplets or semicircular windows in each stage, generally crenellated at top, and covered with a low pyramidal roof. The well-known leaning tower at Pisa is cylindrical, in five stories of arcaded colonnades. In Ireland there are in some of the churchyards very curious round towers.

Tracery. The ornamental filling in of the heads of windows, panels, circular windows, etc., which has given such characteristic beauty to the architecture of the fourteenth century. Like almost everything connected with mediæval architecture, this elegant and sometimes fairy-like decoration seems to have sprung from the smallest beginnings. The circular-headed window of the Normans gradually gave way to the narrow-pointed lancets of the Early English period, and, as less light was afforded by the latter system than by the former, it was necessary to have a greater number of windows; and it was found convenient to group them together in couplets, triplets, etc. When these couplets were assembled under one label, a sort of vacant space or spandrel was formed over the lancets and under the label. To relieve this, the first attempts were simply to perforate this flat spandrel, first by a simple lozenge-shaped or circular opening, and atterward by a quatrefoil. By pierc-

ing the whole of the vacant spaces in the window head, carrying moldings around the tracery, and adding cusps to it, the formation of tracery was complete, and its earliest result was the beautiful geometrical work such as is found at Westminster Abbey.

Transept. That portion of a church which passes transversely between the nave and choir at right angles, and so forms a cross on the plan.

Transom. The horizontal construction which divides a window into heights or stages. Transoms are sometimes simple pieces of mullions placed transversely as cross-bars, and in later times are richly decorated with cuspings, etc.

Traverse. To plane in a direction across the grain of the wood, as to traverse a floor by planing across the boards.

Tread. The horizontal part of a step of a stair.

Trefoil. A cusping the outline of which is derived from a three-leaved flower or leaf, as the quatrefoil and cinquefoil are from those with four and five.

Trellis. Lattice-work of metal or wood for vines to run on.

Trestle. A movable frame or support for anything; when made of a cross-piece with four legs it is called by carpenters a horse.

Triforium. The arcaded story between the lower range of piers and arches and the clere-story. The name has been supposed to be derived from *tres* and *fores*—three doors, or openings—that being a frequent number of arches in each bay.

Triglyph. The vertically channeled tablets of the Doric frieze are called triglyphs, because of the three angular channels in them—two perfect and one divided—the two chamfered angles or hemiglyphs being reckoned as one. The square sunk spaces between the trigylphs on a frieze are called metopes.

Trim. Of a door, sometimes used to denote the locks, knobs, and hinges.

Trimmer. The beam or floor joist into which a header is framed.

Trimmer Arch. An arch built in front of a fireplace, in the thickness of the floor, between two trimmers. The bottom of the arch starting from the chimney and the top pressing against the header.

Tuck-pointing. Marking the joints of brickwork with a narrow parallel ridge of fine putty.

Tudor Style. The architecture which prevailed in England during the reign of the Tudors; its period is generally restricted to the end of the reign of Henry VIII.

Turret. A small tower, especially at the angles of larger buildings, sometimes overhanging and built on corbels, and sometimes rising from the ground.

Tuscan Order. The plainest of the five orders of Classic architecture.

Tympanum. The triangular recessed space enclosed by the cornice which bounds a pediment. The Greeks often placed sculptures representing subjects connected with the purposes of the edifice in the tympana of temples, as at the Parthenon and Ægina.

Under-croft. A vaulted chamber under ground.

United States, Architecture of. The architecture of the whole territory of the republic, which might be considered under the following heads: (1) *Pre-Columbian Era;* Many structures were only of one story, but some were of four or five. From the rude bough wickyup of the Arizona Pai Ute, lightly

abandoned on every change of camp, to the massive and elaborately ornamental stone buildings of the Maya of Yucatan. It is possible, therefore, in America to take up the study of house building where the thread is lost in Europe, and with both follow the line of development from the wickyup to the Parthenon. (2) *Colonial Era;* Influenced by Great Britain, Spain, Holland, Sweden, and France. (3) *Modern Era;* Starting with World's Fair at Chicago in 1893 and culminating in the tall building or "skyscraper" office-building of the twentieth century.

Upset. To thicken, and shorten as by hammering a heated bar of iron on the end.

Vagina. The upper part of the shaft of a terminus, from which the bust or figure seems to rise.

Valley. The internal angle formed by two inclined sides of a roof.

Valley Rafters. Those which are disposed in the internal angle of a roof to form the valleys.

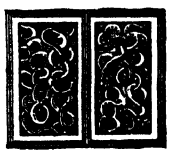
Vane. The weathercock on a steeple. In early times it seems to have been of various forms, as dragons, etc.; but in the Tudor period the favorite design was a beast or bird sitting on a slender pedestal, and carrying an upright rod, on which a thin plate of metal is hung like a flag, ornamented in various ways.

Vault. An arched ceiling or roof. A vault is, indeed, a laterally conjoined series of arches. The arch of a bridge is, strictly speaking, a vault. Intersecting vaults are said to be groined. See *Groined Vaulting* for fuller description of vaults.

Verge. The edge of the tiling, slate or shingles, projecting over the gable of a roof, that on the horizontal portion being called eaves.

Verge Board. Often corrupted into Barge Board; the board under the verge of gables, sometimes molded, and often very richly carved, perforated, and cusped, and frequently having pendants, and sometimes finials, at the apex.

Vermiculated. Stones, etc., worked so as to have the appearance of having been worked by worms.



VERMICULATED

Vestibule. An ante-hall, lobby, or porch.

Vestry. A room adjoining a church, where the vestments of the minister are kept and parish meetings held.

Viaduct. A structure of considerable magnitude, and usually of masonry, for carrying a railway across a valley.

Vignette. A running ornament, representing, as its name imports, a little vine, with branches, leaves, and grapes. It is common in the Tudor period, and runs or roves in a large hollow or casement. It is also called Trayle.

Villa. A somewhat pretentious country house.

Volute. The convolved or spiral ornament which forms the characteristic of the Ionic capital. Volute, scroll, helix, and cauliculus are used indifferently for the angular horns of the Corinthian capital.

Voussoir. One of the wedge-like stones which form an arch; the middle one is called the key-stone.

Wainscot. The wooden lining of walls, generally in panels.

Wall Plates. Pieces of timber which are placed on top of brick or stone walls so as to form the support to the roof of a building.

Wane. The natural curvature of a log or of the edge of a board sawed from an unsquared log.

Warped. Twisted out of shape by seasoning.

Water Table. A slight projection of the lower masonry or brickwork on the outside of a wall a few feet above the ground as a protection against rain.

Weather Boarding. Boards lapped over each other to prevent rain, etc., from passing through.

Weathering. A slight fall on the top of cornices, window-sills, etc., to throw off the rain.

West Indies, Architecture of. The architecture of these islands, their country districts and their towns. Some of the towns are of ancient establishment and contain buildings of the sixteenth century and those which have immediately succeeded them, while others are in architectural character entirely of the nineteenth century, and not of its earliest years.

Wicket. A small door opening in a larger. They are common in mediæval doors, and were intended to admit single persons, and guard against sudden surprises.

Wind. A turn, a bend. A wall is *out of wind* when it is a perfectly flat surface.

Wing. A side building less than the main building.

Withes. The partition between two chimney flues in the same stack.

ARCHITECTURAL TERMS AS DEFINED IN VARIOUS BUILDING CODES

The following definitions have been taken from building codes or laws of various cities. The letters following the definitions indicate the city or code from which they are taken, as follows: (B.), Boston; (C.), Chicago; (D.), Detroit; (L. A.), Los Angeles; (N. Y.), New York; (P. C.), Pacific Coast Uniform Building Code; (P), Philadelphia; (S. F.), San Francisco; (S.), Seattle; (St. L.), St. Louis.

Addition. . . . any change to a structure which increases any of its exterior dimensions. (P.)

Alley. . . . any public thoroughfare in the rear of a lot which fronts on a public street. (St. L.) . . . a public thoroughfare which is less than twenty feet in width, or one which is twenty feet or more in width but unnamed. (S.) . . . any public space, public park or thoroughfare less than sixteen feet but not less than ten feet in width which has been deeded to the public for public use. (P. C.)

Alteration. . . . any change to a structure which does not increase any of its exterior dimensions. (P.) . . . any change, addition or modification in construction or grade of occupancy. (D.) . . . any change or addition. (S. F.) . . . as applied to a building or structure, is any change or rearrangement in the structural parts or in the exit facilities, or any enlargement, whether by extending on any side or by increasing in height, or the moving from one location to another. (N. Y.) . . . any change or addition. (L. A.)

Apartment. (See *Apartment-House.*) . . . room, or suite of two or more rooms, which is or are occupied as a home for one or more persons. (P) . . . shall be taken to mean a room or suite of two or more rooms in a tenement-house occupied or suitable for occupation as a residence for one family doing its own cooking in the apartment or on the premises. One person may be construed to be a family. (St. L.) Apartment or Flat, . . . any number of rooms occupied as the dwelling-place of but one family, except that it shall not include a residence as herein defined. (S) . . . room or suite of rooms in an apartment-house, which is occupied or which is intended or designed to be occupied by one family for living and sleeping purposes. (P. C.) . . . a room or suite of two or more rooms occupied or intended or designed to be occupied as a family domicile. (C.)

Apartment-House. (See *Apartment.*) . . . any building, or portion thereof, containing three or more apartments. For the purpose of this code an apartment-house is a tenement. (P.) Apartment-House or Flat Building, . . . a building containing one or more apartments. (S.) . . . in any building or portion thereof which is designed, built, rented, leased, let or hired out to be occupied, or which is occupied as the home or residence of three or more families living independently of each other and doing their own cooking in the said building, and shall include flats and apartments. (P. C.) Tenement-House and Apartment-House, . . . any dwelling coming within the definition of a tenement-house as defined in the State Tenement House Law. (S. F.) Apartment-House or Tenement-House, . . . a building containing separate apartments for three or more families, and having a street entrance common to all. (L. A.)

Areaway. . . . any sub-surface space adjacent to a building, for lighting or ventilating cellars or basements, or for other purposes. (P.) . . . a space below the surface of the ground adjacent to and outside of a building and used in connection therewith. (S.)

Attic. . . . that part of a building wholly or partly within the roof framing, unfinished, not inhabited nor used for sleeping purposes. (P.) . . . any unfinished space immediately below the roof of a building or an upper room having a height of less than eight feet. (St. L.) Attic or Attic Story, . . . any story situated wholly, or partly in the roof, so designated, arranged or built as to be used for business, storage or habitation. (P. C.)

Basement. . . . a story, or portion thereof, partly but not more than one-half below the average grade of the ground surrounding the building, as shown on the drawings upon which the permit was granted, and counted as a story in determining the height of the building. (P.) . . . shall be taken to mean a story, partly, but not more than one-half below the level of the street grade or ground nearest the building. (St. L.) . . . that portion of a building between floor and ceiling, which is partly below and partly above grade . . . , but so located that the vertical distance from grade to the floor below is less than the vertical distance from grade to ceiling. (P. C.) . . . a story partly, but not more than one-half below the level of the inside sidewalk grade of the street nearest the building. If the floor of such basement is less than two feet below such grade, or if the ceiling of such basement is more than seven feet six inches above said grade, said story shall be classed as the first story of the building in which it occurs; provided, however, that the ceiling height may be raised above the height of seven feet six inches heretofore given, not more than one-third of an inch for every foot of such distance said building is set back from the street-line of the street nearest the building, but in no case shall any rise of ceiling be allowed for any distance beyond thirty feet said building may be set back from the line of the street nearest the building, and in such cases all rises in the basement ceiling shall be computed according to the distance between the street-line and the outside wall of the building nearest to said street-line. Provided, further, that the yard, or ground level, or walks, or other improvements thereon for a distance of twelve feet at every point from all outside walls of said building shall not be lower than eight feet three inches below the floor-level of the first story of said building. (C.) . . . a lower story of which a part, but less than one-half, is below the level of the curb-line of the street or of the general level of the ground. (S. F.) . . . that part of a building not more than 40% nor less than 35% of which is below the mean grade of the curb of the principal street upon which the building abuts, or if it does not abut upon a street, then below the mean grade of the land adjoining the building. When the building abuts on two or more streets the commissioner shall determine which is the principal street. (B.) . . . that story of a building not more than five feet of the height of which at any point is below the grade of the street upon which the principal entrance to the building opens. (L. A.)

Bay. . . . that space within a building between two adjacent rows of columns, or between a row of columns and a bearing-wall. (P.) Bay or Panel, . . . one of the intervals or spaces into which a building front is divided by columns, piers or division-walls. The floor-space included between the intersection of parallel rows of columns or walls of bays at right-angles to each other and the face of a wall between two adjoining pilasters or piers is called a panel. (D.)

Bay-Window. (See *Oriel Window.*) . . . any window extending beyond the wall of a building. (P.) . . . a rectangular, curved or polygonal window supported on a foundation which projects from the balance of the enclosing wall. (D.) Oriel Window, . . . a projecting window similar to a bay-window, but carried on brackets or corbels. The term " Bay-Window " may also be applied to an oriel window, projecting over the street line. (D.) . . . a rectangular, curved or polygonal window, supported on a foundation extending beyond the main wall of the building. (P. C.)

Building. . . . any structure for the support, shelter or enclosure of persons, animals or chattels; and when separated by division walls, from the ground up, and without openings, then each portion of such building shall be deemed a separate building. (St. L.) . . . any structure built for the support, shelter, or enclosure of persons, animals or chattels, and when separated by division walls without openings, each portion so separated shall be deemed a separate building. (S.) . . . any structure built for the support, shelter and enclosure of persons, animals, chattels, or movable property of any kind; and when separated by an "Absolute Fire Separation " each portion of such building so separated shall be deemed a separate building. (P. C.) Building or Structure, . . . any construction the arrangement of which may affect the health, safety or general welfare of man or animals. (S. F.)

Building-Line. . . . a line beyond which property owners or others have no legal or vested right to extend a building or any part thereof, without provision therefor in this code, or without special permission and approval of the proper authorities; ordinarily a line of demarcation between public and private property. (P.)

Cellar. . . . a story, or portion thereof, more than one-half below the average grade of the ground surrounding the building, as shown on the drawings upon which the permit was granted, and not counted as a story in determining the height of the building. (P.) . . . shall be taken to mean a story more than one-half below the level of the street grade or ground nearest the building. A cellar shall not be included in designating the height or number of stories of building referred to in any part of this ordinance. (St. L.) . . . that portion of a building between floor and ceiling which is wholly or partly below grade . . . and so located that the vertical distance from grade to the floor below is equal to or greater than the vertical distance from grade to ceiling. (P. C.) . . . a story more than one-half below the level of the inside sidewalk grade of the street nearest the building. Where the grade of a street adjacent to a tenement-house varies, the average grade of such street opposite the lot containing the tenement-house shall be regarded as the grade of such street within the meaning of this chapter. (C.) . . . a lower story of which one-half or more is below the level of the curb-line of the street, or streets, on which it faces, or of the general level of the ground. (S. F.) . . . when there is a basement, that part or parts of a building below the basement. When there is no basement, that part of a building more than 40% of which is below the mean grade of the curb of the principal street upon which the building abuts, or if it does not abut upon a street not more than 40% below the mean grade of the land adjoining the building. When the building abuts on two or more streets, the commissioner shall determine which is the principal street. (B.)

Club. . . . a building used for the mutual entertainment, recreation and lodging of the members only of an organized club or society and their guests. (S.)

Court. . . . an open unoccupied space other than a yard on the same lot with a building. (P.) . . . an open, unoccupied space on the same lot with a tenement-house other than a yard. (St. L.) Exterior, . . . a court which is bounded on one or more sides by a street or alley. Interior, . . . any court other than an exterior court, as herein defined. (S.) . . . an open, unoccupied space, bounded on two or more sides by the walls of the building. An inner court is a court entirely within the exterior walls of a building. All other courts are outer courts. (P. C.) . . . an open, unoccupied, unobstructed space, other than a yard, on the same lot with a tenement-house; a court entirely surrounded by a tenement-house is an inner court; a court bounded on one side and both ends by a tenement-house, and on the remaining side by a lot line, is a lot-line court; a court extending to a street, alley or yard is an outer court. (C.) . . . an open, unoccupied space other than a yard on the same lot as the building. A court extending to the yard or street is an outer court. A court extending to the lot line is a lot-line court. (S. F.)

Dwelling. . . . any house or building not a lodging-house, tenement, rooming-house or inn; all or any part of which is occupied as a home or residence of a family, or of two families, living independent of each other. (P.) . . . a residence. (S.) . . . a building which shall be intended or designed for or used as the home or residence of not more than two separate and distinct families or households, and in which not more than fifteen rooms shall be used for the accommodation of boarders, and no part of which structure is used as a store or for any business purpose. Two or more such dwellings may be connected on each story and used for boarding purposes, provided the halls and stairs of each house shall be left unaltered and kept open and in use as such. (S. F.) . . . a building intended for the residence of not over two families. (L. A.) . . . Dwelling-Place, . . . a building, or part thereof, which is occupied by one or more families, who live therein and cook their own food upon said premises. (S)

Factory. The term shall include every building in which goods, wares and merchandise are manufactured. (D.) . . . a building used for manufacturing articles by machinery. (S.) . . . a building, the whole or greater portion of which is used for manufacturing purposes. (L. A.)

First Story. (See *Story.*) . . . the story, the floor of which is at or first above the level of the sidewalk, or adjoining the ground. The other stories are to be numbered in regular succession, counting upward. (D.) . . . the first story more than 65% of the height of which is above the mean grade of the curb of the principal street upon which the building abuts or if it does not abut upon a street, the first story of a building, more than 65% of the height of which is above the mean grade of the land adjoining the building. Where there is a basement, that story next above the basement shall be the first story of a building. Where there is a cellar and no basement that story next above the cellar shall be the first story of a building. When the building abuts on two or more streets the commissioner shall determine which is the principal street. (B.)

Flats. (See *Apartment.*) . . . a building of two or more stories containing separate self-contained dwellings, each dwelling having an independent entrance on the level of the street or from an outside vestibule on the level of the first floor. (S. F.) . . . a building of two or more stories containing independent dwellings, each having its own street entrance. (L. A.)

Footing. . . . the spreading course at the base or bottom of a foundation

wall, pier or column. (P.) . . . the projecting course or courses at the bottom of a foundation wall or pier. (D.)

Foundation. (*a*) . . . all that portion of a building or a structure below the top of footings, or basement or cellar floor. (*b*) . . . the earth upon which the structure rests. (D.) . . . shall be taken to mean that portion of a building below ground and in contact with the earth. (St. L.)

Front. . . . that face thereof which contains the principal entrance to said building. (L. A.)

Garage. A public garage shall mean any place where space is rented for the storage of more than two automobiles or motor-driven vehicles. A private garage shall mean any place other than a public garage where motor-driven vehicles are stored. (P.) . . . a building, or portion thereof, in which a motor vehicle is kept for storage, repair or for any other purpose, except that it shall not be considered to include a building, or portion thereof, in which the only motor vehicles kept are in transit or are kept temporarily during the daylight hours only for changing of tires or batteries, or are unused motor vehicles temporarily in storage and containing no inflammable fuel. (S.) . . . a building or portion thereof in which a motor vehicle containing gasoline, distillate or other volatile, inflammable liquid in its tank, is stored, repaired, used or kept. (P. C.)

Grade. . . . the surface of the ground, court, lawn or sidewalks adjoining a building. The "established grade" is the level of the street curb as fixed by the municipality. (P.) The established sidewalk level at the building line of any street, or if the building be not built on the building line of a street, then the exposed surface of the earth adjoining any wall shall be taken to be the grade for that wall. (St. L.) Established Grade, . . . the sidewalk or alley elevation along the property-line as established by public improvements. (S.) Natural Grade, . . . the undisturbed natural surface of the ground. (S.) (1) . . . for buildings adjoining one street only, the elevation of the sidewalk at the center of that wall adjoining the street. (2) . . . for buildings adjoining more than one street, the average of the elevations of the sidewalk at centers of all walls adjoining streets. (3) . . . for buildings having no wall adjoining the street, the average level of the ground (finished surface) adjacent to the exterior walls of the building. All walls approximately parallel to and not more than five feet from a street-line are to be considered as adjoining a street. (P. C.)

Ground Floor. (See *First Story.*) . . . the floor at or near the level of the grade when used for public purposes. (D.)

Height of Building. (*a*) . . . the vertical distance of the highest point of the roof, in the case of flat roofs; and for high-pitched roofs, the average of the height of the gable above the mean grade of the curbs of all the streets, or the mean grade of the natural ground adjoining the building if the said grade or ground is not below the grade of the curb. (*b*) . . . the number of stories in a building, including the basement, but not including the cellar. (P.)

Hospital. . . . any building for housing sick persons, including maternity hospitals, sanitariums, etc. (S.) Hospital or Sanitarium, . . . a building used for the keeping and care of sick, invalid and infirm people, and having accommodation for more than five such people. (S. F.) Hospital, Sanatorium, Sanitarium or Asylum, . . . a building in which sick, demented, injured, infirm, aged or orphaned persons are housed or intended to be housed (L. A.)

Hotel. . . . a building in which is conducted the business of lodging the public and which is occupied by more than six guests or lodgers. (S.) . . . a building or part thereof intended, designed or used for supplying food and shelter to residents or guests and having a general public dining-room or café, or both, and containing more than fifteen guests' rooms. (S. F.)

Lodging-House. . . . a building containing more than fifteen rooms in which persons are or may be accommodated with sleeping apartments for hire, by the day, week or month. (S. F.)

Lot. . . . a subdivision of a block, as shown by a recorded plot of an addition to, or subdivision of, the City, or any portion of land, whether plotted or unplotted, considered as a unit of property and described by metes and bounds; if one or more lots are built upon as a unit of property, they shall, for the purpose of this ordinance, be considered as a single lot. (S.)

Masonry. . . . brick, stone, tile or terra-cotta laid in mortar or concrete. (S.) . . . shall apply to brick, stone, interlocking hollow tiles, concrete or reinforced-concrete construction. (S. F.) . . . includes such parts of a structure as are constructed with stone, bricks of burnt clay, cement, or a sand lime, hollow blocks of burnt clay or concrete, and stone or cinder concrete, both plain and reinforced work. (B.) . . . means brick, stone or concrete. (L. A)

Motion-Picture Theater. (See *Theater.*) . . . any public hall or room in which motion pictures are displayed, in which the seating capacity does not exceed six hundred persons and in which there is no stage or scenery. (N. Y.)

Office-Building. . . . a building divided into rooms, intended and used for office purposes, and no part of which shall be used for living purposes, except by the janitor and his family. (S. F.)

Owner. . . . any person having title to, or control as guardian or trustee of, a building or property. (S.) . . . includes his duly authorized agent or attorney, a purchaser, devisee, and any person entitled to an interest in the property in question. (N. Y.)

Oriel Window. (See *Bay-Window.*) . . . a window that projects from the main line of an enclosing wall of a building and is carried on brackets or corbels. (P. C.)

Panel. (See *Bay.*)

Pent-House. . . . any structure erected on the roof of a building for the purpose of enclosing stairways to the roof, elevator machinery, water tanks, ventilating apparatus, exhaust chambers or other building equipment machinery. (P.) . . . a room constructed above the roof of a building and used exclusively to give head room above a stair, to house elevator machinery, or provide working space above the elevator sheaves. (S.)

Public Hall. . . . a corridor or passageway used in common by all of the occupants of a building. (S.) . . . a hall, corridor or passageway not within an apartment. (C.) . . . a room for public assemblages, not including a theater, having a total seating capacity of one hundred or more persons. (L. A.)

Repairs. . . . the reconstruction or renewal of any existing part of a building, or of its fixtures or appurtenances, by which the strength of the fire risk is not affected or modified. (S. F.) . . . the reconstruction or renewal of any existing part of a building, or of its fixtures or appurtenances. (L A.)

Shaft. . . . includes exterior and interior shafts, whether for air, light, elevator, dumb-waiter or any other purpose; a "vent-shaft" is one used solely to ventilate or light a water-closet compartment, bath-room or pantry. (C.) . . . in a building is any open space other than a court, extending through the building for two or more stories, exterior or interior, whether for light, air, elevator, dumb-waiter or any other purposes. A vent-shaft is one used solely to ventilate or light, or both, a water-closet compartment or bath-room. (S. F.)

Stair-Hall. . . . the stairs, stair landings and those portions of the public halls through which it is necessary to pass in getting from the entrance floor to the top story. (C.) . . . the stairs, stair landings, hallways or passages through which it is customary to pass in going from the entrance to the roof. (S. F.)

Stores. The term "stores" shall include every building used for the sale of goods, wares and merchandise. (D.) A "store building" is a building used wholly or in part for the purposes of exhibiting for sale goods, wares or merchandise. (L. A.)

Story. (*a*) . . . that portion of any building included between the upper surface of any floor and the upper surface of the floor next above. (*b*) A "half-story" is that part of any building wholly or partly within the roof framing; finished and inhabited. (P.) . . . that portion of a building included between the surface of any floor and the surface of the next floor above it, or if there be no floor above it, then the space between such floor and the ceiling next above it. (St. L.) . . . that portion of a building included between the upper surface of the floor next above, except that the topmost story shall be that portion of a building included between the upper surface of the topmost floor and the ceiling or roof above. A basement or cellar shall not be considered a story unless the ceiling thereof is more than five feet above grade. (P. C) . . . that part of a building between the top of any floor level and the top of the floor or roof level next above. (B.) . . . that part of any building comprised between any floor and the floor or roof next above. (N. Y.) . . . that portion of a building between the top of any floor-beams and the top of the floor or ceiling-beams next above. (C.) A "story and a half building" shall be taken to mean a building that is more than one story in height and less than two stories in height, wherein any portion of the space above the first-story ceiling is used or intended to be used or occupied for storage, living or sleeping purposes. (L. A.)

Tenement-House. (See *Apartment-House.*)

Theater. . . . a building which contains seats for the public, and to which an admission fee is charged, and in which movable scenery is used. (S. F.) . . . a room, hall, or auditorium having a stage either with or without scenery, used or designed to be used for the public entertainment of persons, and adapted to the presentation of plays, operas, spectacles, or similar forms of entertainment. (L. A.)

Walls. (See under various kinds of walls.)

Wall, Bearing. . . . a wall which supports any vertical load other than its own weight. (P.) . . . a wall on which joists, beams, girders and trusses of floor or roof-construction rest. (D.) . . . a wall designed to carry, in addition to its own weight, some portion of the roof or floors of a building. (S.) . . . a wall which supports any load other than its own weight. (P. C.) . . . any wall carrying all or part of the interior load of a building. (S. F.) . . . a wall carrying a portion of the interior load of a building. (L. A.)

Wall, Curtain. . . . a non-bearing wall between columns and/or piers and which is not supported by girders or beams. (P.) . . . the non-bearing and enclosing wall of an iron or steel, or reinforced-concrete skeleton frame, or the non-bearing portion of an enclosing wall between piers. (D.) . . . an enclosing wall built and supported between columns or piers, and on girders or other support, and sustaining no weight but its own. (St. L.) . . . a non-bearing wall built between columns and extending through two or more stories without intermediate support. (S.) . . . a non-bearing wall between columns or piers which is not supported by girders or beams. (P. C.) . . . any wall supported at intervals on the frame of a building, or a wall which is self-supporting only on the exterior of a building. (S. F.)

Wall, Division. . . . a bearing wall running between two exterior walls subdividing building into several parts (D.) . . . a masonry wall entirely dividing or separating one building from another. (St. L.) . . . an interior wall dividing a building or extending from the ground to and through the roof. (S.) . . . any wall other than an exterior wall, or a party wall, which extends the full height of a building and through the roof, and such walls shall be constructed in all respects as provided for party walls. Such walls may be bearing walls or self-supporting only. (S. F.) . . . any wall, other than an exterior wall or a party wall which extends the full height of the building and through the roof. (L. A.)

Wall, Exterior. . . . any outside wall which serves as a vertical enclosure of a building, including a party wall when not used in common. (P.) . . . every outer wall or vertical enclosure of a building. (S. F.) . . . every outer wall or vertical enclosure of a building other than a party wall. (L. A.)

Wall, Fire. . . . a wall of solid masonry or reinforced concrete which subdivides a building to restrict the spread of fire and which starts at the foundations and extends continuously through all stories to and above the roof. (P.) . . . a division-wall which extends through and at least eighteen inches above the roof and in which all openings are protected by fire-doors. Also any division or partition-wall dividing spaces into limited areas for fire-protection purposes. (D.) . . . is a wall of masonry or reinforced concrete which subdivides a building to prevent the spread of fire by starting at the foundation and extending continuously through all stories to and above the roof. (P C.) . . . shall apply to all walls built for the purpose of fire-resistance. The term also applies to that portion of walls above roof-surface. (S. F.) . . . is that part of a masonry or reinforced concrete wall extending above the roof, immeately adjoining such wall. (L. A.)

Wall, Fire Division. . . . a wall of solid masonry or reinforced concrete which subdivides a building to restrict the spread of fire, but is not necessarily continuous through all stories nor extended through the roof. (P.)

Wall, Foundation. . . . that portion of an enclosing wall below the first tier of floor-joists or beams nearest to and above the grade-line, and that portion of any interior wall or pier below the basement or cellar-floor. (D.) . . . that part of a wall below the level of the street curb, or, if a wall below the level of the highest ground next to the wall, or, in the discretion of the commissioner, that part or partition-wall below the cellar floor. (B.)

Wall, Non-Bearing. (See *Wall, Curtain.*) . . . a wall designed to carry only its own weight. (S.)

Wall, Partition. . . . an interior non-bearing wall wholly supported at each story. (P.) . . . any wall running at any angle to the bearing-walls

and subdividing the interior of a building into compartments. (D.) . . . any interior wall of masonry. (St. L.) . . . any interior wall other than a division-wall. (S. F.) . . . an interior wall of masonry in a building. (B.) . . . any interior wall in a building other than a division-wall. (L. A.) . . . an interior subdivision-wall. If constructed of other material than masonry, the name or class of the structural material is usually prefixed. (D.)

Wall, Party. . . . a wall which, or portion of which, encroaches upon ground of an adjoining owner and is used jointly or adapted to joint use. (P.) . . . a wall that separates two or more buildings, and used or to be used jointly by separate buildings. (D.) . . . a masonry wall used or built to be used for the common separation or support of adjoining buildings of separate owners. (St. L.) . . . a wall used, or designed to be used, in common by two buildings. (S.) . . . a wall used or adapted for joint service between two buildings. (P. C.) . . . a wall used, or built to be used, in common by two or more buildings. (S. F.) . . . a wall that separates two or more buildings, and is used or adapted for the use of more than one building. (B.) . . . a wall used or erected to be used, in common as a structural wall by two or more adjoining buildings. (L. A.)

Wall, Retaining. . . . a wall used to resist the lateral thrust of any material. (P.) . . . a sub-surface wall built to resist lateral pressure of the adjoining earth and to prevent its caving in. Also any enclosing wall built to resist the lateral pressure of internal loads. (D.) . . . a wall subjected to lateral pressure. (S.) . . . shall apply to all walls constructed for the purpose of holding back or supporting earth. (S. F.)

Wall, Spandrel. . . . an exterior non-bearing wall in skeleton construction built between columns or piers and wholly supported at each story. (P.)

Wall, Thickness. . . . minimum thickness as given in this ordinance and measured on the bed. (D.) . . . the minimum thickness . . . measured between any two floors, or between floor and ceiling or roof. (S. F.) . . . the minimum thickness of such wall. (B.) . . . means the minimum thickness of a wall between the floors and the ceiling or roof of a building. (L. A.)

Warehouse. . . . a building or portion thereof, used principally for the storage of merchandise. (S.) . . . a building used exclusively for the storage of merchandise. (S. F.) . . . a building used for the storage of goods, wares or merchandise. (L. A.) . . . every building used for storage of goods, wares and merchandise. (D.)

Yard. . . . an open, unoccupied space on the same lot with a tenement, rooming-house or dwelling, and which space extends in its full width or depth between opposite lot-lines. (P.) . . . an open, unoccupied space on the same lot with a tenement-house for the full width of the lot. (St. L.) . . . an open, unoccupied space, other than a court, unobstructed from the ground to the sky, except where specifically provided by this code, and on the lot on which a building is situated. (P. C.) . . . an open, unoccupied space on the same lot with a tenement-house, separating every part of every building on the lot from the rear line of the lot. (C.) . . . an open, unoccupied space on the same lot as the house, between the extreme rear line of the house and the rear line of the lot. (S. F.)
